What Is Neuroethics?

Directly and indirectly, neuroscience touches all of our lives, and its influence can be expected to grow. Mental illness is very common, with a lifetime prevalence of at least 12%, perhaps very much higher (Kessler et al. 2007). The incidence of dementia is growing rapidly, due to our aging population and the fact that more than 30% of all people aged over 80 will suffer from it (Peters 2001). These are problems of the brain/mind, and therefore neuroscience seems to hold out the best hope of understanding them, reducing their incidence, and perhaps even of a cure. Other major health and social problems centrally involve dysfunctions of the brain/mind: think of the enormous problems caused by pathological gambling or drug addiction. Even the worldwide obesity epidemic, which has produced a global population in which there are more obese people than there are undernourished (Macey 2006), might be understood as at least partially a problem that neuroscience can illuminate, insofar as overeating is at least partially to be explained psychologically.

Two major research initiatives in neuroscience funded by the US and the EU, respectively, are expected to increase our knowledge about how the brain works, our understanding of diseases and how to cure or at least treat them and thereby accelerate the influence of neuroscientific findings on our lives. The European Human Brain Project (HBP) addresses seven challenges of neuroscience and ultimately aims at computationally simulating the brain (Markram 2013). The US-funded Brain Activity Map (BAM) project seeks "to fill the gap in our knowledge of brain activity at the circuit level, a scale between single neuron and whole brain function" (Alivisatos et al. 2013).

Since the brain is embedded in and interacts with a body, and humans act in relation to other human beings, the neuro-essentialist notion that the brain defines who we are might seem a bit far-fetched. However, there is no doubt that the brain is the biological substrate of central human characteristics like consciousness and morality. Indeed, all human behavior must be understood as the behavior of creatures with minds; there is no aspect of our lives that neuroscience cannot, in principle, help to illuminate. Neuroscience promises to cure disease and perhaps to help us to achieve our goals at a lower cost, but it also promises to help us to understand the kind of creatures we are. By shedding light on the brain, it illuminates our prized rationality, our creativity, our capacity to produce and appreciate art, even our capacity for awe and transcendence. Some people find the prospect tantalizing and attractive; others are fearful that in explaining we might explain

away. Perhaps we will reveal ourselves to be mere automatons, they worry, rather than beings with a dignity.

Neuroscience also holds out the promise of using its techniques to improve ourselves. The pharmaceuticals developed for the treatment of disease may be used by people who are not ill, to make them "better than well" (Elliot 2003). This, too, is a prospect that excites and appeals to people in equal measures. Some see the promise of an exciting future of broader horizons and a technological utopia, others recall the warnings of *Brave New World* and other dystopias.

To raise these questions is already to be doing neuroethics. Neuroethics is systematic and informed reflection on and interpretation of neuroscience, and related sciences of the mind (psychology in all its many forms, psychiatry, artificial intelligence, and so on), in order to understand its implications for human self-understanding and the perils and prospects of its applications.

Neuroethics has developed as a response to the increasing power and pervasiveness of the sciences of the mind. It has been known for centuries that mental function and dysfunction are closely related to neural function and dysfunction (even Rene Descartes, the 17th century philosopher who is now much derided by neuroscientists for his theory that mind was immaterial, made the connection between brain and mind a central part of his theory). Our knowledge of the nature of the relationship came largely from post-mortem studies of the brains of people known to have particular cognitive problems: Thus, areas responsible for linguistic processing were identified in the 19th century. But it is only recently, with the advent of non-invasive means of studying the living human brain (and especially with the development of functional magnetic resonance imaging, which enables the real-time study of the brain as the person engages in particular tasks), that our knowledge has really begun to expand rapidly. Today the Society for Neuroscience has nearly 42,000 members, all of whom actively working in neuroscience, and holds an annual conference attended by more than 30,000 delegates. There are more than 220 journals dedicated to neuroscience; around 25,000 papers on the brain are published annually. Our knowledge of the brain, and therefore of ourselves, grows rapidly, and with it our powers to intervene in the mind. Neuroethics is at once fascinating and urgent.

Neuroethics is commonly held to have two branches, the *ethics of neuroscience* and the *neuroscience of ethics* (Roskies 2002). Under the first heading, neuroethics is concerned not only with ethical issues in the practice of neuroscience (ethical issues in subject recruitment, in the conduct of neurosurgery, in the reporting of neuroscientific findings in academic journals and the popular press, and so on), but also with ethical issues in the application of neuroscience and the technologies and techniques it helps to develop, inside and outside the clinic. Under this heading, therefore, fall concerns about the use of psychopharmaceuticals, or other techniques (direct current stimulation or implantable electrodes, say) to treat mental illness or to enhance the capacities of those without a diagnosable illness. By the neuroscience of ethics Roskies meant, principally, the ways in which neuroscience might help us to understand morality itself: the principles by which we reason, the relative contribution of emotional and non-emotional processes to moral thought, and

perhaps even the extent to which moral thought sometimes goes wrong. Above, we suggested that neuroethics should not be identified with reflection on neuroscience alone, but be expanded to include reflection on the other sciences of the mind. Correlatively, we suggest that the neuroscience of ethics should also be understood broadly, encompassing not only the ways in which the science of the mind can help us to understand moral reasoning, but also the ways in which it might help us to understand other perennial philosophical issues (the nature of knowledge, the ways in which self-control is exercised and how it may be lost, free will and the mind/brain, and so on). This is, in practice, how neuroethics has been conducted in the past, and it is this broad range of issues that are canvassed in this handbook.

If neuroethics is not to be overwhelmed by the hype that characterizes too much of the popular coverage of neuroscience, it must have a strong and realistic grasp on what is actually possible, on the nature of the brain and its relationship to the mind, and on how best to understand neuroscientific work. The volume therefore begins by canvassing the philosophical foundations of neuroscience, while another section covers the powers and limitations of neuroimaging, our major source of evidence concerning the brain.

About the Editors

Jens Clausen, Institute for Ethics and History of Medicine, University of Tübingen, Tübingen, Germany

Jens Clausen, Dr. rer. nat. (PhD), is professor at the Institute for Ethics and History of Medicine, University of Tübingen, head of the neuroethics group, and managing director of the Clinical Ethics Committee of the University Hospital Tübingen. He also is a member of the Center for Integrative Neuroscience (CIN) and the research ethics commission. Prof. Clausen studied biology and philosophy in Tübingen and was junior researcher and member of the interdisciplinary network project The Status of the Extracorporeal Embryo at the Centre for Ethics and Law in Medicine, Freiburg, Germany, and the Chair for Ethics in Life Sciences, Tübingen. From 2004 to January 2008 he headed the Junior Research Group, Human Nature and Its Relevance in Biomedical Ethics, at the University of Freiburg.

He is guest editor of a double special issues on ethical aspects of neurotechnologies published by Springer in the journal *Neuroethics* (Vol. 6, No. 3, 2013). He has published, edited, or co-edited eight books and is author of more than 50 papers in renowned journals including *Nature*, *European Journal of Neuroscience*, *Current Opinion in Psychiatry, and Neuroethics*.

Neil Levy, The Florey Institute of Neuroscience and Mental Health, University of Melbourne, Parkville, Australia

Associate Professor Neil Levy is an Australian Research Council Future Fellow, based at the Florey Institute of Neuroscience and Mental Health, Australia. He is also director of research at the Oxford Centre for Neuroethics. Assoc. Prof. Levy is a philosopher with very wide-ranging interests. He has published more than 100 papers, mainly on applied ethics, free will, philosophy of mind and psychology, as well as continental philosophy, political philosophy, and other topics. He is the author of seven books, include *Neuroethics* (Cambridge University Press, 2007), *Hard Luck* (Oxford University Press [OUP], 2011), and *Consciousness and Moral Responsibility* (OUP, 2014). In 2009, he was awarded the Australia Museum Eureka Award for Research in Ethics.

Foundational Issues in Cognitive Neuroscience

Foundational Issues in Cognitive Neuroscience: Introduction

1

Gualtiero Piccinini

Contents

Abstract

Cognitive neuroscience raises several foundational issues. A first issue is how to account for our feeling that we are in control of our actions. A second issue is how to account for the relation between the mind and the nervous system. A third issue is how cognitive neuroscience supports its conclusions. A fourth issue is how cognitive neuroscience explains phenomena. A fifth issue is how to account for the notions of neural representation and neural computation.

Is the Mind Causally Efficacious in the Physical World?

To many people, the mind appears to be very different in nature from the physical stuff of which nervous systems are made. The mind seems to be made of *mental* stuff, or *experience*, stuff that strikes many people as . . . fundamentally different from physical stuff. Perhaps the mind is a nonphysical substance, or at least a collection of nonphysical properties that attaches to the nervous system. But if

the mind is fundamentally different from physical substances and properties, it becomes unclear how mental states could possibly be caused by physical stimuli (as in perception) or cause physical responses (as in behavior). This is the problem of mental causation, which is discussed in ▶ Chap. 5, “Mental Causation” by Holly Anderson.

One view is that mental stuff, no matter how fundamentally different it is from physical stuff, can causally interact with physical stuff. This is called *interactionist dualism*. Interactionist dualism has the advantage of vindicating our feeling that our mind interacts with the physical world, but it has the remarkable disadvantage of making it mysterious how this occurs. No one has ever explained how something nonphysical could possibly interact with something physical. In addition, interactionist dualism implies that cognitive neuroscience cannot explain cognition and behavior—the true explanation lies in the nonphysical (mental) stuff, which presumably is not accessible to standard neuroscientific methods.

Another view is that mental stuff is causally inert after all—or at least it does not causally interact with the *physical* stuff of which our nervous systems are made, or if it is *caused by* physical events, it *causes no* physical events of its own. Maybe mental states interact with each other, but they never interact with anything physical. This view—called epiphenomenalism—frees cognitive neuroscience to explain our behavior in terms of neural mechanisms and processes, and some cognitive neuroscientists have endorsed it. Unfortunately, epiphenomenalism also implies that our mind has nothing to do with our behavior, which many people find hard to swallow.

The last possibility is that the mind is *physical*—presumably, the mind is some aspect of the nervous system and its activity. Those who think the mind is fundamentally different from physical stuff are just wrong. This view is called *physicalism*. Like interactionist dualism, physicalism vindicates our feeling that our mind interacts with the physical world. Like epiphenomenalism, physicalism implies that cognitive neuroscience can explain cognition and behavior. But physicalism raises new questions as well.

How Does the (Physical) Mind Relate to the Nervous System?

Even if the mind is physical in a broad sense (physicalism), there remains the question of how, more precisely, it is metaphysically related to the nervous system. This issue is discussed in the entry by Aizawa and Gillett.

One possibility is that mental properties are just physical properties of the nervous system. This view is called *reductionism*. All that cognitive neuroscience has to do in order to explain cognition and behavior is to find the physical properties of the nervous system that are identical to the mental properties. Reductionism has an appealing simplicity, but—at least in its strongest forms—it has a couple of disadvantages as well. First, (strong) reductionism does not sit well with the prevalent explanatory strategy within cognitive neuroscience, which is mechanistic (see below); this is because fitting a phenomenon within a multilevel mechanistic explanation involves both showing how the phenomenon is produced by a series of

organized components, which sounds reductionist, *and* showing how the phenomenon contributes to a higher-level mechanism, which sounds antireductionist. Second, (strong) reductionism does not sit easily with the plausible view that cognition may be physically realizable by systems that possess no nervous system—for instance, silicon-based robots.

Another possibility is that mental properties are *realized* by physical properties of the nervous system without being identical to them. According to this view, cognitive neuroscience may still explain cognition and behavior by finding the physical properties of the nervous system that realize mental properties, but this leaves open the possibility that other physical systems—say, silicon-based robots—also realize the same mental properties in some physically different way. This view also seems to fit well the mechanistic explanatory style that prevails in neuroscience.

A third possibility is that mental properties are higher-level physical properties that emerge in nervous systems in addition to their lower-level physical properties—emergent properties are novel and irreducible to lower-level properties. This is called (strong) emergentism. Emergentism vindicates the common feeling that there is something special about our mind, but it introduces a mystery about how the emergent properties emerge. In addition, the emergent properties appear ontologically redundant: once the lower-level properties have done their causal work, there does not seem to be any causal work left over for the emergent properties to do. If this causal exclusion argument is correct, emergentism collapses back into epiphenomenalism—the view that denies the mind any influence on the physical world.

How Does Cognitive Neuroscience Support Its Conclusions?

Cognitive neuroscientists intervene on the nervous system, collect data, and draw conclusions. What this means and the epistemic risks involved are discussed in the entry by Jacqueline Sullivan.

A cognitive neuroscience experiment requires subjects to engage in a cognitive task. After that, behavior and neural activity are recorded using a variety of techniques that include both neuroimaging methods and neurophysiological recording. Computational models may also be used to understand how subjects may be able to process solve the given task. A prediction is made—for instance, about whether a certain area of the brain is involved in a cognitive task. In the best-case scenario, the data collected will adjudicate between these three competing hypotheses and point to the one that is best supported by the data.

The data from an experiment will serve their function only to the extent that they are reliable and valid. Data are *reliable* just in case they are unlikely to support false conclusions. Data are *valid* just in case they support the conclusions that they were intended to support. The intended conclusion may be about human cognition in the wild, whereas the data may be collected from rats or fruit flies operating in a constrained laboratory environment. The extrapolation from the latter to the former carries inductive risk.

Imaging techniques face a specific set of epistemic challenges, which must be handled appropriately. First, the experimental paradigms used in conjunction with imaging technology may or may not be sufficient to individuate the cognitive function under investigation. Second, typical neuroimaging techniques do not measure neural activity directly, but some correlate of it, which raises the question of what the exact correlation is between the two. Third, neuroimaging data must be processed before they are usable to draw any conclusion, and this data processing may introduce mistakes and biases that affect the reliability and validity of the conclusions. In summary, experiments in cognitive neuroscience are fraught with epistemic risks, which we should consider when evaluating the conclusions that are drawn from them.

How Does Cognitive Neuroscience Explain?

There is an old idea about scientific explanation: it consists of deriving a phenomenon from the laws of nature together with initial conditions. The entry by Kaplan discusses why this old idea is poorly suited for explanation in cognitive neuroscience and proposes a replacement. For starters, cognitive neuroscience rarely discovers or invokes anything resembling laws of nature. A better account is that cognitive neuroscience explains by providing multilevel mechanisms.

A mechanism is an organized collection of components, each of which plays a role in producing a phenomenon. A mechanistic explanation explains a phenomenon by showing how the roles played by each component, when the components are organized in the appropriate way, produce the phenomenon. Each role of each component of a mechanism is a phenomenon of its own, which may be explained mechanistically by going down one level and looking at the component's sub-components, the roles they play, and the way they are organized. By the same token, a phenomenon produced by a mechanism may play a role in a larger mechanism, whose behavior may be explained mechanistically by going up one level and looking at what a mechanism contributes to the larger system that contains it as a component.

Cognitive neuroscience explains cognition and behavior in terms of multilevel neural mechanisms. If we start from cognition and behavior, those are phenomena to be explained in terms of neural systems (cortical areas, cerebellum, brainstem, etc.), their roles, and their organization. The roles played by neural systems, in turn, are phenomena to be explained in terms of their components (cortical columns, nuclei, etc.), their roles, and their organization. Going down to even lower levels, we find neural networks, neurons, and their components. If and when we understand cognition and behavior at all these levels, we will have a multilevel mechanistic explanation of cognition and behavior.

The above picture assimilates explanation of cognition and behavior to explanation in other mechanistic sciences, such as other areas of physiology and engineering. Is there anything that distinguishes neurocognitive explanation from other mechanistic explanations?

How Does the Nervous System Think?

An important part of the explanation for how nervous systems manage to think is that they collect information from the organism and the environment, use that information to construct representations, and perform computations on such representations. Nervous systems have the distinctive function of performing computations over representations in order to control the organism—that sets them apart from most other mechanisms. The entry by Maley and Piccinini elaborates on this point.

To begin with, nervous systems possess receptors that respond to a wide variety of physical stimuli: light, sounds, odors, pressure, and more. These receptors transduce these physical stimuli into spike trains—sequences of neuronal signals that encode information about the physical stimuli. Neural signals are transmitted to the central nervous system, where they are processed. Such processing—called neural computations—extracts information that is implicit in the signals and combines such information with internal information about the organism's needs, beliefs, and desires—all of which are also encoded as states of the central nervous system. The outputs of neural computations are updated internal states as well as motor outputs—the behaviors of the organism.

This is how cognitive neuroscience explains cognition and behavior—as the outcome of computations over representations performed by multilevel neural mechanisms. Or at least, this is how current cognitive neuroscience explains some aspects of cognition and behavior.

Conclusion and Future Directions

Cognitive neuroscience is an exciting field in the middle of a growth spurt. It collects evidence at multiple levels of mechanistic organization by performing sophisticated experiments using innovative techniques. It integrates such evidence from multiple levels into multilevel mechanistic explanations. It explains cognitive phenomena mechanistically in terms of neural computations operating on neural representations.

There remains room for debate and further work on how to understand cognitive neuroscience, the explanations it gives, their relation to psychological explanations, and the role of the mind in physical world.

Introduction

Talk of levels is prevalent in biology and neuroscience. Investigators in the life sciences routinely deploy various notions of levels including levels of organization, levels of complexity, levels of mechanisms, levels of processing, levels of description, and levels of abstraction. Some of these notions are terminological variants of one another. Others play importantly distinct roles. Some are ontological, describing aspects of the phenomena or target systems under investigation. Others are epistemic, referring to features of the theories, generalizations, and models that scientists build in order to describe, predict, and explain those phenomena. This chapter provides an overview of some of the most common characterizations of levels found in neuroscience, with a specific focus on how levels of organization are invoked in relation to explanation. After characterizing the dominant philosophical approaches to thinking about levels and explanation, the relative advantages of embracing the view of levels embodied by the mechanistic perspective are highlighted. Next, several pressing challenges facing the mechanistic approach are surveyed and how they might be met is briefly explored. Finally, the chapter discusses how the mechanistic approach affords a fruitful viewpoint on another, seemingly unrelated, notion of level frequently invoked in neuroscience – that of Marrian levels of analysis.

By way of introduction, consider one prominent notion of level in the biological sciences – *level of biological organization*. Many biologists have emphasized the importance of hierarchical levels of organization in living systems (e.g., Lobo 2008; MacMahon et al. 1978; Novikoff 1945; Woodger 1929). The idea of hierarchical levels of organization is now established in biology and forms a cornerstone of modern biological theory. General biology textbooks (e.g., Sadava et al. 2009) invariably begin by introducing the biological world as consisting of stratified levels arranged hierarchically such that a particular level of biological organization serves as a sublevel for the next higher level: atoms assemble to form molecules, which in turn assemble into macromolecules, which assemble into cells, which assemble into tissues, which assemble into organs, which assemble into systems, which assemble into organisms, which assemble into populations, which assemble into communities, and so on. The idea of distinct levels of organization is canonical in biology.

Many cognitive scientists and neuroscientists similarly acknowledge the relevance of levels and hierarchical organization for understanding complex systems such as computers, networks, brains, and human organizations (e.g., Simon 1996; Churchland and Sejnowski 1992; Findlay and Thagard 2012; Holland 2000; Sporns 2010). For example, Herbert Simon (1996), a pioneer in cognitive science and artificial intelligence, influentially argues that the concept of hierarchy is the key concept in complex systems research. The concepts of hierarchy and levels are tightly linked: levels are positions in hierarchies and hierarchies are ordering schemes in which elements are arranged at different levels according to some principle or criterion. Churchland and Sejnowski (1992) likewise maintain that the notion of levels plays a fundamental role in neuroscience, serving to structure both how research problems are conceived and how neural systems are investigated.

Numerous investigators have also highlighted how comprehending complex systems, especially complex information-processing systems like the brain, demand an approach that is either carried out at the appropriate level of description for the system under investigation (Anderson 1972; Carandini 2012) or successfully integrates multiple levels of analysis or system description (Bechtel 1994; Bermudéz 2005, 2010; Dawson 1998; Marr 1982; Sporns 2010). Strikingly, even one of the stated goals of neuroscience research articulated in the *Society for Neuroscience's* mission statement is to "advance the understanding of the brain and the nervous system. by facilitating the integration of research directed at all levels of biological organization" (http://www.sfn.org/about/mission-and-strategic-plan). Clearly, many brain researchers and cognitive scientists appreciate that the notion of levels comprises a critically important part of their conceptual toolkit.

Finally, philosophers of science have argued that a dominant form of explanation in biology and neuroscience is mechanistic explanation, which inherently exhibits a *multilevel* structure involving entities and activities occupying multiple levels of organization (e.g., Bechtel 2008; Bechtel and Richardson 1993/2010; Craver 2007; Winther 2011).

Despite the ubiquity and operational importance of various concepts of levels in biology and neuroscience, it is not always perfectly clear how these different concepts should be understood. Interestingly, confusion surrounding notions of levels is not a recent phenomenon – it has a long history (e.g., Bunge 1977). Despite considerable philosophical discussion of the topic, open questions remain. The aims of this chapter are to survey several prominent notions of levels and explanation and highlight the advantages of embracing a mechanistic perspective concerning levels in neuroscience.

Basic Distinctions and Defining Questions

Before proceeding, it is important to flag a basic distinction that will be relied upon in what follows. As mentioned above, the term "level" is ambiguous in science – in one context "level" might refer to the relationship between temporal stages in a causal or information-processing sequence, while in another context the term might refer to the relationship between scientific theories. Nevertheless, a basic distinction between *ontological levels* and *epistemic levels* can begin to impose some order on this diversity. In his useful taxonomy of levels, Craver draws an equivalent distinction between *levels of science* and *levels of nature* (Craver 2007, p. 171). Levels of science subsume relationships among the basic *products* or output of scientific research (e.g., models and theories) and the basic *units* or institutional divisions of science (e.g., research fields and disciplines). For example, the proposal that string theory is at a lower level than the theory of genetic drift posits something about the relationship among levels of science. These are *epistemic levels*. By contrast, levels of nature refer to relationships among *phenomena* (e.g., properties, states, events, and objects) in the natural world that are targets of

scientific investigation. For example, the claim that quarks occupy a lower level than DNA asserts something about the relationship among levels of nature. Claims about levels of nature carry ontological commitments. These are *ontological levels*.

One further resource to be recruited in this chapter is the following set of defining questions about levels also outlined by Craver (2007, pp. 163–195):

The relata question: What is the nature of the relata in the proposed relationship between levels?

The ranking question: What makes a given element occupy a different (higher or lower) level than some other element?

The parity question: What makes two (or more) elements occupy the same level?

These questions identify plausible theoretical desiderata that any adequate philosophical account of levels must satisfy. Consequently, they will be used as benchmarks for assessing the various approaches to levels considered in what follows.

Explanation and Levels: The Traditional Approach

The basic logical empiricist account of explanation – the *covering law model* of scientific explanation (Hempel and Oppenheim 1948; Hempel 1965) – and its associated account of theory reduction (Nagel 1961) continue to exert a profound influence on contemporary philosophical discussions of these topics (e.g., Woodward 2003, 2009; Brigandt and Love 2012). Despite well-known limitations, one lasting legacy of these once-dominant accounts is the view of levels they have inspired.

The Covering Law Model of Explanation

The underlying idea of the covering law model is that to explain something is to show how to derive it in a logical argument. Accordingly, a scientific explanation should be readily expressible as a logical argument in which the *explanandum-phenomenon* (that which is being explained) appears as the conclusion of the argument and the *explanans* (that which does the explaining) appears as the premises. The premise set comprising the explanans typically includes statements describing the relevant empirical conditions under which the phenomenon obtains, known as *initial conditions*. One additional requirement of the model is that at least one of the premises must describe a *general law* required for the derivation of the explanandum. The explanans is supposed to provide good evidential grounds for expecting the occurrence of the explanandum-phenomenon. The account can be depicted schematically as follows (Hempel 1965, p. 336):

$$\frac{\begin{array}{c} C_1, C_2, \ldots, C_k \\ L_1, L_2, \ldots, L_r \end{array}}{\therefore E}$$

where $C_1, C_2, \ldots, C_k$ are premises describing initial conditions and $L_1, L_2, \ldots, L_r$ are premises expressing the relevant general laws. In its original formulation (Hempel and Oppenheim 1948), the explanandum-phenomenon E is characterized as a *deductive* consequence of the premises. This specific version of the account has come to be known as the *deductive–nomological* or *D–N model*. Hempel later extended the account to apply to explanations involving the subsumption of events under statistical rather than deterministic laws. According to the *inductive–statistical* or *I–S model* (Hempel 1965), good statistical explanations are ones in which the explanandum-phenomenon is rendered expectable with a high degree of probability based on the premises. The covering law model is typically treated as the general account, subsuming both D–N and I–S style explanations as species (for additional discussion, see Woodward 2009).

In its most general formulation, the covering law account is intended to apply both to the explanation of particular events that are restricted in space and time such as the Space Shuttle Challenger crash or the extinction of the dinosaurs, as well as to the explanation of general regularities or laws such as the explanation of Kepler's laws of planetary motion in terms of more basic laws of Newtonian mechanics (in combination with a specification of initial conditions concerning the distribution of planetary bodies in the solar system) or the explanation of Mendel's laws of inheritance in terms of more fundamental generalizations from molecular genetics. Derivations of one or more sets of laws (comprising a theory) from another set of laws (comprising another theory) are known as *intertheoretic reductions*. Given that the covering law account is designed to apply to the explanatory relationships holding among laws or theories, it should not be too difficult to see how a corresponding account of theory reduction emerges.

The Nagelian Model of Theory Reduction

According to the traditional logical empiricist perspective, explanation and theory reduction are closely linked (For additional discussion of reduction and related topics, see ▶ Chap. 4, "Realization, Reduction, and Emergence: How Things Like Minds Relate to Things Like Brains"). Just as the D–N model ties successful explanation to the presence of a deductive or derivability relationship between explanans and explanandum statements, so too successful reduction is tied to the presence of a deductive relationship between two theories. Intertheoretic reduction is thus naturally treated as a special case of deductive–nomological explanation.

Most discussions of theory reduction in philosophy of science have been heavily influenced by Nagel's model of theory reduction (Nagel 1961, pp. 366–397). One of Nagel's central aims was to elucidate the logical or explanatory relationships between the scientific disciplines and especially the relationships between the theories of those disciplines. Levels talk is quite naturally recruited to characterize his objective. Nagel wanted to provide an account of the conditions that must obtain in order for a theory (or law) from a higher-level science such as psychology to be reduced to a theory (or law) from a lower-level science such as neuroscience or biophysics. The basic answer Nagel defends is that a lower-level theory serves to reduce (and also *explains*) a higher-level theory when it can be used to logically derive the lower-level theory. More formally, in order for a suitably axiomatized theory T_1 (the *reducing theory*) to reduce, and thereby explain, a suitably axiomatized theory T_2 (the *reduced theory*), T_2 must be logically entailed by or derivable from T_1:

$$T_1 \vdash T_2$$

What this means is that all the laws and all of the observational consequences of the reduced theory T_2 can be derived from information contained in the reducing theory T_1. Nagel (1961) argues that the relationship between classical thermodynamics and statistical mechanics cleanly fit this account of reduction. He maintains that the laws of thermodynamics (e.g., the Boyle–Charles law relating temperature, pressure, and volume in a gas) can be derived from – and so are successfully reduced to and explained by – more fundamental laws of statistical mechanics (e.g., laws characterizing the aggregate behavior of the constituent molecules). Since the terminology invoked by the reduced and reducing theories often differs in appreciable ways, the so-called bridge principles are required to establish identities between the terms of the two theories. For example, a bridge principle might link terms from thermodynamics such as "heat" with those of statistical mechanics such as "mean molecular energy." Finally, because the reduced theory will typically only apply over a restricted part of the domain of the reducing theory (Nagel 1961) or at certain limits (Batterman 2002), *boundary conditions* that set the appropriate range for the reduction are often required. For example, the regularities captured by the higher-level gas law of thermodynamics only obtain for a restricted range of systems under a restricted range of conditions (e.g., gases operating within a certain specified range of pressures and temperatures). Without specifying boundary conditions, most derivations of higher-level laws (in the reduced theory) from the lower-level laws (the reducing theory) would be unsuccessful.

Because statistical mechanics provides a lower-level (i.e., molecular) explanation of macroscopic thermodynamic quantities such as work, heat, and entropy, and the regularities these quantities enter into, it is generally understood to provide a clear example of the reduction of a higher-level theory to a lower-level one (for recent discussion, see Dizadji-Bahmani et al. 2010; Callendar 1999; Sklar 1999). Whatever its successes might be, however, Nagel's model of reduction provides no

account of levels. No answers are given to the key questions about levels outlined above (see section "Basic Distinctions and Defining Questions"). Consequently, we are left in a state of uncertainty regarding what, according to the theory reduction model, constitutes a level; how levels are demarcated; and the principle by which levels are ordered or ranked. It was therefore left to others, namely, Oppenheim and Putnam (1958), to develop an account of levels built upon the traditional logical empiricist framework of explanation and reduction – a conception of levels that remains influential to this day.

Oppenheim–Putnam Levels

Now we are in a suitable position to understand the account of levels that the logical empiricist tradition has inspired, explore its general limitations, and assess its appropriateness as a characterization of the kinds of levels encountered in neuroscience. One lofty goal of logical empiricism was to unify the sciences. Philosophical interest in the possibility of a unified science that would, among other things, provide a general theoretical understanding spanning the full range of natural and social phenomena predates logical empiricism (for further discussion, see Cat 2013; Causey 1977). However, what differentiates the logical empiricists from others with the same objective is that they thought the best strategy to achieve unification involved clarifying the relationships between the various sciences, especially the logical relationships among the theories of those sciences (e.g., Carnap 1955).

Not surprisingly, logical empiricists naturally gravitated towards *reduction* as the relation of choice to characterize the connections between the disciplines and the theories of those disciplines. In "Unity of Science as a Working Hypothesis," Oppenheim and Putnam (1958) present a specific proposal for the unification of science based on successive *micro-reductions* of various higher-level laws or theories (many logical empiricists equate these terms) to a basic or lowest-level physical theory about elementary particles and their interactions. In the course of laying out their reductionistic program, they develop an influential conception of levels subject to considerable discussion in general philosophy of science (e.g., Potochnik and McGill 2012; Rueger and McGivern 2010; Walter and Eronen 2011) and more focused debates about the relation between specific sciences such as psychology and neuroscience (e.g., Bermudéz 2005, 2010; Bickle 2008; Fodor 1974).

Oppenheim and Putnam's (1958) conception of levels is primarily rooted in the existing divisions between the various sciences. Given their general avoidance of metaphysical or ontological concerns, logical empiricists tend not to characterize the natural world itself as comprised of levels of organization. Instead, they identify levels of organization indirectly through the scientific disciplines that investigate them. Along these lines, Oppenheim and Putnam (1958) propose that the different branches or disciplines of science – and the domains of entities associated with the distinctive theories of those branches – each comprise a different level of organization within a single global hierarchy. In total, they identify six levels. Subatomic

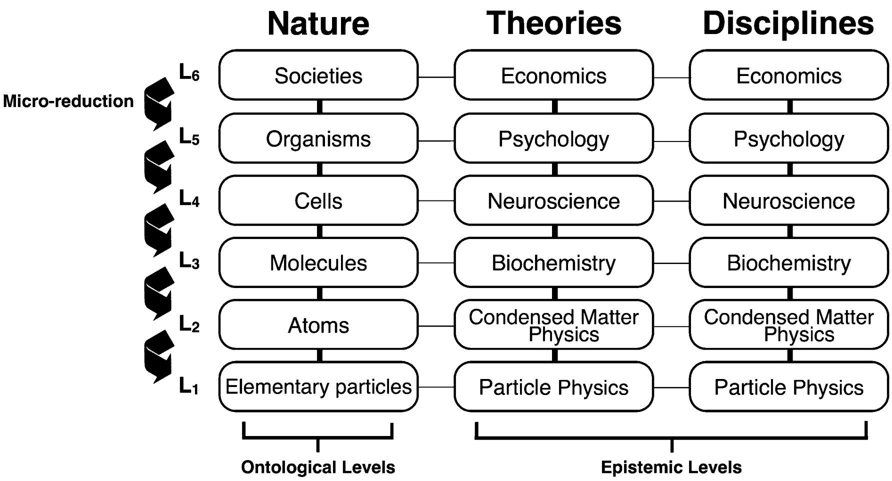

Fig. 2.1 Oppenheim and Putnam's levels hierarchy

physics (also called *particle physics*) occupies the bottom position in the hierarchy as it addresses phenomena at the lowest level of organization, atomic physics (also called *condensed matter physics*) comes next as it targets phenomena at the next highest level, with other disciplines such as biochemistry, biology, psychology, and sociology targeting phenomena at successively higher levels of organization.

For the sake of clarity, these different aspects or dimensions of Oppenheim and Putnam's proposed levels hierarchy – the different disciplines, theories, and domains of objects associated with those theories – can be represented separately (Fig. 2.1). However, it is important to understand that these closely interrelated aspects do not each constitute individual hierarchies in their own right. Oppenheim and Putnam clearly intend to propose only a single, global hierarchy. This more intricate picture helps to illuminate the structure of their account. In particular, it clarifies how the account primarily concerns epistemic levels. Although levels of nature appear to warrant an ontological construal, the fact that this aspect of their levels hierarchy is most accurately described in terms of the domains of objects or ontological posits associated with specific disciplines or theories makes an epistemic interpretation highly plausible (for a similar interpretation, see Craver 2007). Representing things in this way also helps to reveal a costly assumption built into their account, namely, that each organizational level of nature (Fig. 2.1, left column) is associated with one and only one scientific discipline that specifically targets phenomena at that level (Fig. 2.1, middle column) and one and only one corresponding theory specific to that level (Fig. 2.1, right column). The problems associated with this assumption will be discussed in more detail below.

How then does this picture of levels relate back to the goal of scientific unification? Oppenheim and Putnam propose as a "working hypothesis" that the unity of science can be achieved in principle by reducing the theory (or theories) of each higher-level discipline in the proposed hierarchy to those of the next

lower-level discipline in succession until one reaches the lowest-level discipline of fundamental physics dealing with elementary particles. In particular, they argue that this scientific hierarchy supports a special type of theory reduction – *micro-reductions* – which they argue is a satisfactory method for achieving unification. Micro-reductions are a subset of theory reductions in which the objects or entities included in the domain of the reduced theory T_2 are structured wholes that decompose into elements, all of which belong to the domain of the reducing theory T_1 (Oppenheim and Putnam 1958, p. 6). The proposed levels hierarchy is thus ordered so that the scientific discipline (or corresponding theory) addressing entities at a given level can potentially serve as a *micro-reducer* of the discipline (or corresponding theory) addressing entities at the next highest level in the specific sense that the entities from the higher level are decomposable into entities at the lower level. On their account, neuroscience (Fig. 2.1, level 4) serves as a potential micro-reducer of psychology (Fig. 2.1, level 5) – the branch of science at the next highest level in their hierarchy – because the domain of objects countenanced by the discipline of psychology (or by psychological theory) (i.e., organisms) can themselves be decomposed into the entities belonging to the domain of objects countenanced by neuroscientific theory (i.e., cells). The theory at this level can in turn be micro-reduced by the next lowest level, which in turn can be subject to its own micro-reduction, and so on, until some fundamental level is reached.

How well does this account address the aforementioned theoretical desiderata for an account of levels? According to the Oppenheim and Putnam account, the primary relata in the proposed levels relationship are any one or all three of the aspects identified above: object domains, theories, or disciplines. Because they posit a one-to-one-to-one correspondence between levels of nature (domains), theories, and disciplines, these formulations are largely interchangeable. This is their answer to *the relata question*. Next, levels are distinguished and rank ordered by part-whole decomposition. According to their view, any element occupying a higher level is a structured whole that decomposes into parts that are elements in the next lower level of the hierarchy. Cells reside at the next higher level to molecules in virtue of the fact that cells decompose into molecules, molecules are at the next higher level to atoms because molecules decompose into atoms, and so on. Thus, their answer to *the ranking question* is that a given element occupies a different (lower or higher) level than some other element based on a part-whole relationship.

One further feature related to how levels are ranked in the Oppenheim–Putnam hierarchy warrants mention. As indicated above, the levels hierarchy they depict is best understood as a single *global* hierarchy in the sense that every natural system or object must fit into this hierarchy at one and only one particular level. As Bechtel (2008) aptly describes it, the traditional conception assumes that "levels are strata spanning the natural world, with each entity determinately either at the same level or at a higher or lower level than some other entity" (2008, p. 147). It provides a global identification of levels. Finally, according to their account, any whole that is decomposable into parts belonging to a given level will occupy the same level as any other whole that is equivalently decomposable into parts belonging to that same

level (e.g., a pod of Orcas and a colony of ants belong to the same level since they both decompose into individual organisms). Thus, their answer to *the parity question* also clearly depends on part-whole decomposition.

Problems with the Traditional Approach

Oppenheim and Putnam's account has been subject to a considerable amount of criticism. Some have questioned assumptions about the nature of reduction embodied in the account (e.g., Fodor 1974). Others have challenged its descriptive adequacy as an account of reduction in science as it has proved difficult to locate real examples that satisfy the account (e.g., Sklar 1967). Still others have raised issues concerning its oversimplified portrayal of the relationships between the various sciences and the theories and explanandum phenomena of those sciences (e.g., Wimsatt 2007). Here focus will be placed on the specific problems with Oppenheim and Putnam's scheme as an account of levels of organization in neuroscience.

The first major criticism focuses on the fact that Oppenheim and Putnam assume a meaningful demarcation of levels can be based on the divisions between the scientific disciplines, and relatedly, that different sciences exclusively address phenomena at different levels. This overly regimented picture has appeared to many commentators as difficult to maintain (e.g., Bechtel 2008; Craver 2007; Wimsatt 2007). One need only consider the obvious fact that many disciplines, like physics, deal with phenomena at a great diversity of scales ranging from the microscopic (e.g., quarks and neutrinos) and mesoscopic (e.g., turbulent flows) to the macroscopic (e.g., galaxies and supernovas). In such cases, it is difficult to discern a clear sense in which all these phenomena occupy the same level (Bechtel 2008, p. 143). Similarly, biology and neuroscience appear to address phenomena at a range of levels (on most reasonable accounts of levels) (e.g., Churchland and Sejnowski 1992; Craver 2007; Schaffner 1993).

Consider the action potential as a paradigmatic example from neuroscience. The target phenomenon itself arguably resides at the cellular level in the Oppenheim–Putnam hierarchy, since an action potential is defined as a transient change in the neuron's overall membrane potential – a property of the cell as a whole. This much is consistent with their scheme. Yet the current mechanistic understanding of the action potential in neuroscience encompasses multiple levels including molecular and atomic levels (Fig. 2.2). Recall that according to their scheme, each of these levels is proprietary to other disciplines, not neuroscience. Neuroscientists have extensively investigated how ion flow underlying action potentials depends on the behavior of proteins embedded in the cellular membrane acting as voltage-gated ion channels (Hille 2001). These membrane components unambiguously reside at the macromolecular level. Ion channels in turn have their own internal working parts, which have also been subject to intense study in neuroscience, including molecular subunits or domains that support different gating and sensor functions (e.g., Catterall 2000). Finally, other critically important aspects of ion channel function

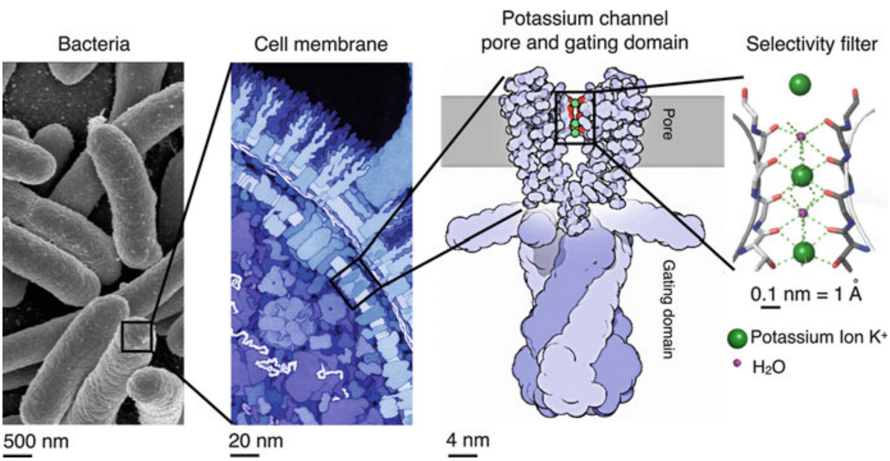

Fig. 2.2 Neuroscience research spans multiple levels of organization (Source: Wikipedia, David S. Goodsell, and RCSB Protein Data Bank. With permission)

such as selectivity for a single ion species are conferred by atomic-scale structural properties of components inside the ion-conducting pore of these channels (e.g., Choe 2002; Doyle et al. 1998). This example of multileveled investigation and explanation in neuroscience is the rule rather than the exception in neuroscience (for additional examples, see Craver 2007). As in the case of physics, it appears deeply misguided to characterize all of these structures as residing at the same level simply because they are addressed by investigators in the same home discipline of neuroscience.

A closely related difficulty stemming from the fact that research in neuroscience typically spans multiple levels is that Oppenheim and Putnam's account is not descriptively adequate since it fails to include the broad range of levels of organization that are vitally important to contemporary neuroscience. They make the strong assumption that there is a one-to-one correspondence between level of phenomena investigated and discipline, but neuroscience clearly does not fit this simplistic scheme. An accurate description of the full range of levels of phenomena addressed in neuroscience would at very least include the circuit level, population level, area level, and network level. In this regard, Oppenheim and Putnam's account is at best incomplete (Craver 2007, p. 173).

A final criticism of Oppenheim and Putnam's account is that it is inconsistent with the fact that different disciplines often target phenomena at the same size or scale (Craver 2007, p. 176). As indicated above, this is especially true for disciplines that investigate phenomena at a wide spectrum of size levels, which notably includes neuroscience. As discussed above, in studying the mechanistic structure of ion channels from the single cell level all the way down to the angstrom scale, neuroscientific investigations overlap in substantial ways with other disciplines including molecular biology, biochemistry, and biophysics in terms of the level of phenomena they target.

Oppenheim and Putnam's account of levels has appeared to many to be fraught with difficulties that are not easily overcome (e.g., Bechtel 2008; Craver 2007). Consequently, many philosophers of neuroscience have chosen to look elsewhere for a conception of levels appropriate to neuroscience.

Explanation and Levels: The Mechanistic Approach

Although the covering law account dominated philosophical thinking about the nature of scientific explanation and reduction for most of the twentieth century, the mechanistic approach is now in ascendancy as a view about explanation in the life sciences including neuroscience. There are two primary reasons for the growing acceptance of the mechanistic approach. First, for many years now, there have been a number of well-known general objections to the covering law account that essentially remain unanswered. These challenges are familiar enough that rehearsing them here is unnecessary (for a comprehensive review, see Salmon 1989). The second reason for abandoning the covering law model centers on the basic fact that laws, and by extension law-based explanations, are few and far between in biological science in general and neuroscience in particular. Instead, there is widespread agreement among philosophers that when investigators in these scientific fields put forward explanations, they often seek to identify the mechanism responsible for maintaining, producing, or underlying the phenomenon of interest. In other words, they seek to develop *mechanistic explanations*. Consequently, over the past two decades or so, philosophers have increasingly focused on the important role that mechanistic explanation plays in the biological sciences including neuroscience (e.g., Bechtel 2008; Bechtel and Richardson 1993/2010; Craver 2007; Machamer et al. 2000). Given its increasing prominence, it should be relatively unsurprising that the mechanistic perspective has also been mined for philosophical insights about the nature of levels.

There are a number of mechanistic accounts in the literature, which differ in subtle and not-so-subtle ways. Nevertheless, a central idea common to all accounts that adequate mechanistic explanations must include descriptions of three key elements: the component parts, the activities of those parts, and the overall organization of those parts and activities that give rise to the behavior of the mechanism as a whole.

Mechanistic Levels

The mechanistic framework embodies a distinctive perspective about levels of organization in mechanisms. The mechanistic view starts with an assumption common to many philosophical theories of levels (e.g., Oppenheim and Putnam 1958; Wimsatt 2007) that the relationship between lower and higher levels is best understood in terms of a compositional or part-whole relationship (Craver 2001;

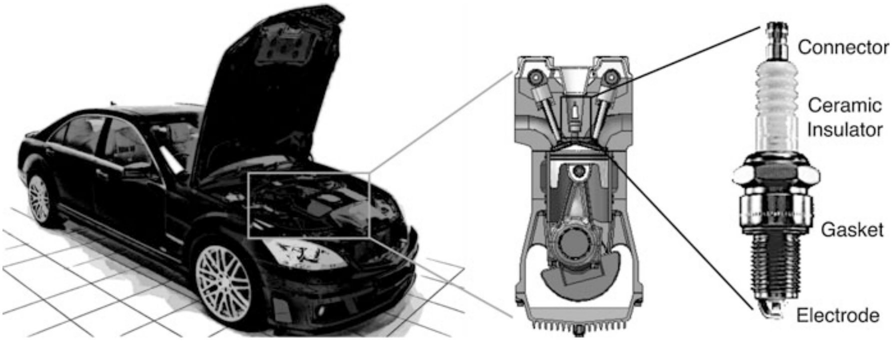

Fig. 2.3 Nested levels of organization in a mechanism

Craver and Bechtel 2007, p. 550). Critically, however, it goes beyond these accounts by imposing an additional requirement that the lower-level parts cannot be any arbitrary parts resulting from any decomposition whatsoever. Instead, the parts occupying the lower level must be working components of the mechanism residing at the higher level.

The mechanistic approach differs from Oppenheim and Putnam's account in one further respect. Since the mechanistic treatment of levels focuses squarely on part-whole relations within the mechanisms themselves to demarcate levels, it is an account of ontological levels (in contradistinction to Oppenheim and Putnam's account of epistemic levels). According to Craver's mechanistic view, "[i]n levels of mechanisms, the relata are behaving mechanisms at higher levels and their components at lower levels" (Craver 2007, p. 189). Bechtel similarly maintains that "[i]t is the set of working parts that are organized and whose operations are coordinated to realize the phenomenon of interest that constitute a level" (Bechtel 2008, p. 146).

Consider how this account of levels applies to a simple mechanism such as the internal combustion engine (Fig. 2.3). The entire working engine system is the overall mechanism responsible for, among other things, producing motion in a car. The engine is composed of a variety of functional parts including intake valves, spark plugs, and pistons, all of which perform activities that contribute in specific ways to the overall performance of the mechanism. According to the mechanistic account of levels, the engine as a whole occupies a higher mechanistic level than that of the component parts, which occupy the next lowest level.

Importantly, mechanistic levels are *nested* in the sense that what comprises a part relative to some higher-level mechanism may itself also be a mechanism relative to some yet lower-level part (Bechtel 2008; Craver 2007). Consider again the internal combustion engine example (Fig. 2.3). While the spark plug is a component in the engine as a whole, and therefore occupies the next lower level, it is also a mechanism in its own right that supports decomposition into its own organized set of parts including the electrode, ceramic insulator, and gasket.

It is also important to recognize that levels of organization in mechanisms are *local* in the sense that they are only defined relative to a given mechanism

(Bechtel 2008; Craver 2007). The mechanistic approach to levels does not propose global strata spanning the natural world as the traditional approach does. In this respect, it is a modest account of levels of organization.

Several important consequences follow from the local identification of levels. First, questions about whether components of a given mechanism (or the mechanism as a whole) reside at a higher, lower, or the same level as entities outside the mechanism are not well defined (Bechtel 2008; Craver 2007). In a particular mechanistic context, two arbitrary elements are deemed to reside at the same mechanistic level only if they are components in the same mechanism. They occupy a higher or lower level depending on how they figure into a componential or part-whole relation within a mechanism. Critically, the mechanistic account provides no resources to compare levels outside a given mechanism.

Second, entities of the same physical type can occupy different levels depending on the specific mechanistic context (Bechtel 2008; Craver 2007). Recruiting the previous example, carbonyl oxygen atoms lining the inner wall of the narrow, approximately 12-Å-long segment of the potassium ion channel pore (Fig. 2.2, rightmost panel) are critical parts of the mechanism for the action potential. These oxygen atoms function as precisely spaced binding sites in the channel's selectivity filter that enable the free passage of potassium ions and impede the movement of sodium ions. As components, they reside one level below the action potential mechanism as a whole. But oxygen atoms are also components of molecules making up many other cellular structures including the cell membrane. As the cell membrane is itself also a component of the action potential mechanism, and so occupies a level below the mechanism as a whole, its own parts will occupy a yet lower level (two levels below the mechanism as a whole). Thus, oxygen atoms reside at different levels depending on how they are employed in the mechanism.

Third, the local character of mechanistic levels allows for a different view of reduction than the traditional theory reduction model (Bechtel 2008). Whereas the traditional approach assumes that higher-level theories can be reduced in succession to increasingly lower levels until some fundamental level is reached, which in turn grounds all the higher levels, the mechanistic approach rejects this global account of reduction. While mechanistic explanations are reductionistic in the sense that they appeal to lower-level parts and their operations to explain some higher-level behavior of the mechanism, they are *locally* reductionistic because there is no single fundamental level that globally grounds all higher levels of mechanisms.

How well does this account address the aforementioned theoretical desiderata? The mechanistic perspective offers clear answers to all three defining questions. First, in contrast to the traditional approach, the mechanistic approach offers an ontologically committed answer to the relata question. The relata are entities that, depending on the particular mechanistic context, play roles either as entire mechanisms or components. Second, the mechanistic answer to the ranking question is that entities are assigned to different levels based exclusively on their part-whole status within a given mechanism. Entire mechanisms occupy higher levels and their components reside at immediately lower levels. As indicated above, the

mechanistic perspective also offers a limited answer to the parity question: entities occupy the same level if they are components in the same mechanism.

Finally, is the mechanistic approach to levels appropriate to neuroscience? Craver has defended this claim in detail (Craver 2007, pp. 165–170), stating that levels of mechanisms best illuminate the sense in which explanations in neuroscience extend across multiple levels. He defends this claim in part by carefully reviewing the multilevel mechanistic explanation of memory formation and spatial learning involving long-term potentiation (LTP) of neuronal synapses in the hippocampus. Instead of walking through that well-known example to show the appropriateness of the account of mechanistic levels, we can again recruit the example discussed above to demonstrate the same thing. Figure 2.2 depicts four distinct levels of mechanisms. There is the level of individual *Escherichia coli* bacteria, the level of the single cell, the level of components of single cells (e.g., ion channels), the level of components of ion channels (e.g., selectivity filters), and the level of components of selectivity filters (carbonyl group oxygen atoms). The specific mechanistic explanation of the action potential makes essential appeal to the last three of these levels. As this and other examples in the literature demonstrate, the mechanistic account of levels provides an accurate characterization of at least one critically important kind of level in neuroscience.

Problems with the Mechanistic Approach

As indicated above, the mechanistic approach to levels offers no means to globally assess level relations beyond the boundaries of a given mechanism. This result will seem especially unsatisfactory to those expecting an account of levels to provide such global assessments and could therefore be viewed as a major deficiency of the account. Proponents of the mechanistic perspective have anticipated this concern and offer two responses. First, they point out that accounts of general or global levels of organization are problematic in their own right. While the project sounds plausible in principle, difficulties emerge when it comes to the actual task of placing all manner of objects into a single levels hierarchy. For example, it is difficult to make sense of the idea of comparing the levels of disparate things like galaxies, elephants, old-growth redwoods, and earthworms. The mechanistic account abandons this project. Second, they maintain that their modest account does the job for which it was intended: it sufficiently captures the sense of levels of mechanisms central to neuroscience research, and this alone should justify its adoption (Bechtel 2008). However, this response merely deflects rather that addresses the worry, because one might continue to hold that any account of levels worth its salt must do more than this. It thus appears that a resolution of this issue demands some prior agreement about what should be expected from an account of levels. Given the state of the dialectic, however, consensus will be difficult to attain.

Another potential shortcoming of the mechanistic account of levels is its treatment of the parity question. Recall that, according to the mechanistic perspective, things occupy the same level only when they are components in the same

mechanism or they stand in a componential relation within a mechanism. This has extremely unintuitive consequences. For example, two objects of the same physical type possessing exactly the same properties will not occupy the same level, if they are not related as components in the same mechanism. Consider the potassium channel example again (Fig. 2.2). According to the mechanistic account, there is no sense in which type-identical H_20 molecules in the cell membrane and in the selectivity filter – both of which are constituents of the same neuron – occupy the same level. This kind of highly counterintuitive result might be taken as evidence that something is deeply problematic with the mechanistic account of levels. Despite these potential limitations, there is much to recommend the mechanistic view of levels as an account of levels in neuroscience.

Levels of Analysis: A Mechanistic Perspective

Another distinct notion of levels that figures prominently in discussions of explanation in neuroscience is the notion of *levels of analysis*. This is the notion of levels at the core of David Marr's (1982) enduring computational framework (For additional discussion of computational issues in neuroscience, see ▶ Chap. 6, "Neural Representation and Computation"). Numerous investigators have since emphasized how understanding the brain requires an approach that successfully combines multiple distinct levels of analysis (Bechtel 1994; Bermudéz 2005, 2010; Carandini 2012; Dawson 1998; Sporns 2010). Nevertheless, some investigators have taken Marr's hierarchical framework to entail an autonomous computational-level explanation of cognitive capacities insensitive to mechanistic details about how such capacities are realized in the brain (e.g., Dror and Gallogly 1999; Rusanen and Lappi 2007). This section briefly sketches how the mechanistic approach affords a fruitful viewpoint on the notion of levels of analysis and, in particular, how it serves to combat a widespread but ultimately mistaken interpretation of Marr's influential framework according to which it supports the idea of an autonomous level of computational explanation. For an expanded discussion of the mechanistic approach to computational explanation in neuroscience, see Kaplan (2011).

Autonomous Computational-Level Explanation?

The idea of an autonomous level of computational explanation has a long history in philosophy and cognitive science (e.g., Fodor 1974; Johnson-Laird 1983; Pylyshyn 1984). According to this perspective, computational explanations of human cognitive capacities can be constructed and confirmed independently of details about how these capacities are implemented in the brain. This claim is also routinely couched in terms of levels. It is often said that the computational-level explanations of psychology are autonomous from implementation-level explanations produced

in neuroscience in the sense that evidence concerning underlying neural organization place no constraints on the shape such higher-level explanations can take.

Time has shown this autonomy claim to be fundamentally mistaken. In particular, scientific efforts to construct autonomous computational accounts unconstrained by data from neuroscience, which could then be mapped back on to real neural mechanisms, are increasingly replaced by psychological models and theories tightly constrained by neuroscientific data. In the absence of constraints derived from what is known about brain structure and function, neuroscientists have been unable to discover the implementations for computational processes posited by high-level psychological theories. This pattern of failure seriously undermines the strict division of intellectual labor assumed by proponents of an autonomous level of computational explanation.

In philosophy, traditional computational functionalism bolstered the idea a *level of autonomous computational explanation*. Functionalists have long maintained that psychology can proceed with its explanatory goals independently of neuroscience. They compare psychological processes to software running on a digital computer. According to the analogy, the brain merely provides the particular hardware on which the cognitive software happens to run, but the same software could be implemented in many other hardware platforms. If the goal is to understand the structure of the software (i.e., what computations are being performed), figuring out the hardware is irrelevant and unnecessary. Despite the fact that it used to be the dominant position in philosophy of mind, functionalism has come under serious challenge. While these lines of argument have run their course, one last arm in the defense of autonomous computational-level explanation remains. It centers on a view about *levels of analysis* famously proposed by the neuroscientist David Marr.

Marr's Levels of Analysis

Marr (1982) distinguishes three levels of analysis intended to apply to information-processing systems ranging from digital computers to the brain: the *computational level* (a specification of the input–output function being computed), the *algorithmic level* (a specification of the representations and computational transformations defined over those representations), and the *implementation level* (a specification of how the other levels are physically realized) (Fig. 2.4).

Unfortunately, several aspects of Marr's own discussion of the relationships between these levels have reinforced the idea of an autonomous level of computational explanation. First, he repeatedly prioritizes the relative importance of the computational level:

> [I]t is the top level, the level of computational theory, which is critically important from the information-processing point of view. The reason for this is that the nature of the computations ... depends more upon the computational problems to be solved than upon the particular hardware in which their solutions are implemented (1982, p. 27).

This privileging of the computational level, coupled with the fact that his preferred methodology is top–down, moving from the computational level to the

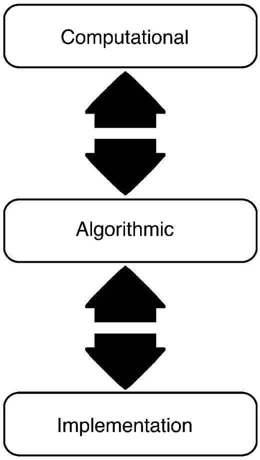

Fig. 2.4 Marr's levels of analysis

algorithmic, and ultimately, to implementation, has fostered the idea of an autonomous level of computational explanation. Second, in some passages, Marr appears to claim that there are either no direct constraints between levels or that the operative constraints are relatively weak and only flow downward from the computational level – claims that are clearly at odds with the mechanistic view. For instance, he states that: "since the three levels are only rather loosely related, some phenomena may be explained at only one or two of them" (1982, p. 25). If computational explanations were unconstrained by one another in this manner, this could be used to draw a conclusion about an explanatorily autonomous level.

When Marr addresses the key explanatory question of whether a given computational model or algorithmic description is appropriate for a specific system under investigation, however, he begins to sound much more mechanistic. On the one hand, his general computational framework clearly emphasizes that the same computation might be performed by any number of algorithms and implemented in any number of diverse hardware systems. And yet, on the other hand, when the focus is on the explanation of a particular cognitive capacity such as human vision, Marr appears to firmly reject the idea that any computationally adequate algorithm (i.e., one that produces the same input–output transformation or computes the same function) is equally good as an explanation of how the computation is performed in that particular system. Consider that after outlining a computational proposal for the extraction of zero-crossings in early vision, Marr and Hildreth immediately turn to a determination of "whether the human visual system implements these algorithms or something close to them" (Marr and Hildreth 1980, p. 205; see also Marr et al. 1979; Marr 1982). This is not an ancillary task. They clearly recognize this to be a critical aspect of their explanatory account. For Marr, sensitivity to information about properties of the human visual system (e.g., the response properties of retinal ganglion neurons) is crucial not only for building successful computer vision algorithms, but also for building successful explanations. According to Marr, the ultimate adequacy of these computational and algorithmic

specifications as explanations of human vision is to be assessed in terms of how well they can be brought into registration with known details from neuroscience about their biological implementation. Marr thus appears to part company with those who maintain that computational explanations are autonomous and unconstrained by evidence about underlying neural systems.

Open questions certainly remain about Marr's computational framework and its relation to explanation in neuroscience that go well beyond the scope of the current chapter. However, this brief exploration of the topic should demonstrate that the mechanistic perspective has great potential to illuminate other kinds of levels in neuroscience besides levels of organization.

Conclusion and Future Directions

There are numerous different kinds of levels in neuroscience that play a variety of important roles. Resources from the mechanistic approach can help to elucidate many of these. It has been argued that the mechanistic approach offers a distinctively useful view about levels of organization in neuroscience. More briefly, it was argued that the mechanistic framework also provides a fruitful perspective on Marrian levels of analysis. A cluster of important questions concerning levels and mechanisms remain open and worthy of further philosophical investigation. One such open question concerns whether global levels of organization can exist in tandem with locally defined mechanistic levels, or whether the two are mutually exclusive, as the current debate implies. This question will be difficult to evaluate until a suitably refined account of global levels is available. Another wide open question concerns how the mechanistic approach handles other kinds of levels including levels of abstraction. Practically everyone acknowledges that scientific explanation – including mechanistic explanation – involves abstraction to some degree, yet how this is compatible with the basic tenets of the mechanistic account remains uncertain. All of these questions about levels are of fundamental importance in philosophy of science and provide worthwhile targets of future exploration.

Abstract

Neuroscience is a laboratory-based science that spans multiple levels of analysis from molecular genetics to behavior. At every level of analysis, experiments are designed in order to answer empirical questions about phenomena of interest. Understanding the nature and structure of experimentation in neuroscience is fundamental for assessing the quality of the evidence produced by such experiments and the kinds of claims that are warranted by the data. This chapter provides a general conceptual framework for thinking about evidence and experimentation in neuroscience with a particular focus on two research areas: cognitive neuroscience and cognitive neurobiology.

Introduction

Neuroscience advances our understanding of the brain and behavior primarily by means of experimentation. Findings from neuroscience shape how we think about the nature of cognition, behavior, diseases and disorders of the mind and brain, consciousness, moral responsibility, and free will. Interpretations of data obtained from neuroscience have the potential to inform diagnostic and treatment decisions and impact assessments of moral culpability and legal responsibility. If the interpretations that neuroscientists make on the basis of data are not warranted, then any claims put forward or decisions made on the basis of that data will lack justification.

Understanding the nature and structure of experimentation in neuroscience and evaluating the explanatory/interpretive claims of neuroscience is crucial for avoiding such epistemological pitfalls. By bringing together insights from the philosophy of neuroscience, the philosophy of scientific experimentation, epistemology and theoretical work in neuroscience and psychology, this chapter puts forward a conceptual framework for thinking about evidence and experimentation in contemporary neuroscience. While the primary focus will be representative examples of experiments undertaken in cognitive neuroscience and cognitive neurobiology, some of the basic lessons are also relevant to experiments conducted in other laboratory-based areas of neuroscience.

Neuroscience and the Experimental Process

One way to think about experimentation in neuroscience and science more generally is as a process, which we may refer to simply as "the experimental process" (See Sullivan 2009). What are the aims of this process? In the simplest terms, the aim of experimentation is to produce data to discriminate among competing hypotheses about a phenomenon of interest. The data from an experiment will serve this function only to the extent that the process of producing those data was *reliable* and the claims made upon the basis of those data are *valid* (See section "Reliability and Validity" below). A worthwhile place to begin to think about evidence and experimentation in cognitive neuroscience and cognitive neurobiology is to say something about the nature of the kinds of claims about phenomena these two areas of science are interested in supporting and the basic types of experiments we find there.

Basic Structure of Experiments: Cognitive Neuroscience

The aims of *cognitive neuroscience* are, roughly, to locate regions of the brain that subserve cognitive functions, to identify patterns of connectivity between different brain regions, and to understand the processing of information through the brain. Cognitive neuroscience combines the conceptual-theoretical framework and

experimental paradigms of cognitive psychology with structural and functional neuroimaging and electrophysiological recording techniques. Experimentation in cognitive neuroscience is based on several basic assumptions. First, organisms have specific kinds of cognitive capacities. Second, these cognitive capacities may be individuated by appropriately designed experimental tasks. Third, for any given cognitive capacity that can be delineated experimentally, it is possible to locate the neural basis of that cognitive capacity in the brain. Identifying the neural basis of a cognitive capacity is assumed to be achievable by correlating (a) subjects' behavioral performance on experimental tasks or their subjective reports with (b) measurable brain activity.

Experiments in cognitive neuroscience combine the use of experimental paradigms/cognitive tasks of cognitive psychology with computational models, neuroimaging, and electrophysiological techniques. A typical experiment in cognitive neuroscience often begins by pointing to previous findings in the empirical literature pertaining to the nature of a specific cognitive function (e.g., face recognition) and the brain area(s) thought to subserve it. These findings are then used as a basis to make testable predictions that are often formulated as competing correlational claims. An example of an empirical question might be: Is the perirhinal (PrC) cortex involved in face recognition? To address this question, an investigator will make predictions about what brain activity in the PrC during a face recognition task ought to look like if it is indeed the case that the PrC is involved. For example, three competing hypotheses may prevent themselves: h_1: Activity in the PrC is increased compared to baseline activity (or activity on a different cognitive task), h_2: Activity in the PrC is decreased compared to baseline activity (or activity on a different cognitive task), and h_3: There is no change in PrC activity compared to baseline activity (or activity on a different cognitive task) (null). In the best-case scenario, the data will adjudicate between these three competing hypotheses and point to the one that is best supported by the data.

While different procedures exist for correlating the behavioral expression of a cognitive function with neural activity (e.g., evoked response potentials (ERPs), positron emission tomography (PET)), by far the most widely employed technology in contemporary cognitive neuroscience, and the one that both philosophers and neuroscientists themselves have questioned the reliability of, is functional magnetic resonance imaging (fMRI). In a typical fMRI experiment, a subject is placed into a magnetic resonance imaging (MRI) scanner and trained in an experimental paradigm. An experimental paradigm is roughly a standard set of procedures for producing, measuring, and detecting a cognitive capacity in the laboratory that specifies how to produce that capacity, identifies the response variables to be measured during pre-training, training, and post-training/testing, and includes instructions on how to measure those response variables using appropriate equipment. It also specifies how to detect a cognitive capacity when it occurs by identifying what the comparative measurements of the selected response variables have to equal in order to ascribe that capacity to a subject (Sullivan 2009). Given that a subject placed in an MRI scanner is physically constrained, the experimental paradigms used in conjunction with fMRI have historically been computer-based

tasks in which the stimuli are presented to subjects on a flat-screen monitor. Subjects elicit behavioral responses to these stimuli or answer questions about them, depending on the instructions provided to them, typically by means of pressing a button.

During task performance or response elicitation, the investigator "scans" the subject's brain, focusing on one or several regions of interest (ROIs). The investigator assumes that when a subject performs a task capable of individuating a discrete cognitive capacity, there will be an increase in neural activity compared to baseline activity in those brain regions involved in task performance. To detect such increases in activity, cognitive neuroscientists rely on the blood-oxygen level dependent (BOLD) response signal. The basic idea is that an increase in neural firing in a given region of the brain triggers a hemodynamic response such that blood is delivered to that area at a more rapid rate than blood that nourishes less active neurons. This increase is accompanied by an increase in oxygen utilization and thus an increase in the amount of deoxygenated blood in the region activated compared to oxygenated blood in the surrounding regions. This difference is used as a contrast for distinguishing areas of heightened activity from areas of less heightened activity. While the subject is in the scanner, sample scans of the brain are taken across a selected time course. Time points of sampling are intended to be coordinated as closely as possible with features of the experimental paradigm such as stimulus presentation and the relevant response output (e.g., button pressing). Once enough data has been collected, investigators pre-process the data in order to eliminate experimental artifacts (e.g., motion of subject while in scanner) and increase signal-to-noise. The data are then processed using statistical analysis techniques (e.g., univariate analysis). The statistically analyzed data is then used as a basis for discriminating among competing functional hypotheses about the brain areas under investigation.

Basic Structure of Experiments: Cognitive Neurobiology

A primary aim of cognitive neurobiology is to discover the cellular and molecular mechanisms of learning and memory (e.g., Sweatt 2009). Cognitive neurobiology combines the behavioral techniques of experimental psychology and electrophysiological, pharmacological, genetic, and protein analysis techniques. A basic set of assumptions informs experimentation in cognitive neurobiology. First, all organisms, from the most simple to the most complex, learn and remember. Second, different forms of learning and memory are detectable by appeal to observable changes in behavior, and may be individuated by appropriately designed experimental learning paradigms. Third, many if not all forms of learning and memory require changes in synaptic strength. Fourth, the changes in synaptic strength that underlie learning and memory are mediated by changes in protein activity and gene expression.

Cognitive neurobiological experiments typically test both correlational and causal or mechanistic claims. Oftentimes an experiment will begin with a question of

whether synaptic, cellular, or molecular activity in the brain *is implicated in* changes in the behavior of an organism or a synapse. For example, in a typical behavioral experiment, an investigator will make predictions about what the measurable changes in cellular and molecular activity and in behavior as a result of training organisms in an experimental paradigm ought to look like in order to establish a correlation between the two factors. Once a correlation between two measurable factors has been established, an investigator typically undertakes intervention experiments. Intervention experiments test predictions about the impact of blocking cellular and molecular activity (with either pharmacological or genetic techniques) on the changes in behavior observed from training organisms in the experimental paradigm. Examples of representative competing hypotheses usually take the following form: h_1: Blocking molecular activity is accompanied by measurable changes in behavior that indicate the learning has been blocked, h_2: Blocking molecular activity is accompanied by measurable changes in behavior that indicate that learning is not blocked, or h_3: Blocking molecular activity results in other measurable changes in behavior that are unexpected (e.g., partial blockade). Again, ideally, the data will adjudicate between the competing hypotheses, discriminating the one that is best supported by the data.

The experimental process in both cognitive neuroscience and cognitive neurobiology is heavily informed and shaped by evidence emanating from other scientific disciplines, including cellular and molecular neuroscience, genetics, psychology, physiology, biochemistry, neuroanatomy, and systems neuroscience. Evidence from these areas serves as a basis for making predictions, formulating testable hypotheses, designing experiments to test those hypotheses, and interpreting the data obtained from such tests. Generally speaking, cognitive neuroscientists and cognitive neurobiologists aim to design experiments to test their predictions and to adjudicate between competing claims about phenomena of interest. When we ask whether neuroscientists succeed at this goal, we are asking whether experimentation in neuroscience is sufficient to yield the data requisite to achieve it.

The Experimental Process

If we want to determine if cognitive neuroscience and cognitive neurobiology are knowledge-generating, it is insufficient to look exclusively at textbook descriptions or reviews of neuroscientific findings. The best unit of analysis is the individual research paper, because it is as close as we can get to the experimental process (without visiting the lab). More specifically, evaluating the merits of already published research papers, which in neuroscience is the aim of lab meetings and journal clubs, is the first step toward answering the question of whether the interpretive or explanatory claims being made in a given research paper are warranted by the data.

Although we often take it for granted that each and every scientist ensures the integrity and reliability of the experimental process himself/herself, it is important to remember that the peer-review process exists in part, because scientists are fallible.

A scientist may believe he/she has adequately tested a hypothesis in instances in which he/she has overlooked potential confounding variables or has failed to exclude or neglected to consider alternative explanations for the results. While peer-review is intended to catch such errors, it offers no full-proof guarantee that science produces knowledge, because individuals on peer-review boards are human and thus fallible, too.

However, even with our unit of analysis being an individual research paper, our access to the experimental process is limited. The introduction provides us with insight into the assumptions that informed a given research study and the origin(s) of the empirical question(s) that the study aims to answer. The methods section provides details about the subjects or objects of the study (e.g., college-age human beings, adult male Wistar rats) and the materials, tools, and techniques used. The results section simply conveys the outcomes of using the methods to answer the empirical question(s). These outcomes are not raw data; they are statistically analyzed data that are typically represented in pictures, charts, and diagrams. The discussion section teases out the implications of the study and attempts to situate the findings within the relevant literature. However, oftentimes the kinds of things that may compromise the knowledge-producing capacity of the experimental process of a given research study are hidden from view. The task is upon us to make the aspects of the process that may potentially compromise the knowledge outcomes of the study (e.g., problematic or unwarranted assumptions, investigator errors, equipment malfunctions, mathematical errors, errors of reasoning and analysis) explicit and to do as thorough a probe of the state-space as possible in order to rule out the possibility that errors were made – to make certain the data can be used to support the interpretative or explanatory claims that the investigators aim to make on the basis of the study.

An appropriate set of analytic tools and a strategy for their application may guide the way. While such tools are not antidotes to error, they at least point us in the direction of where to look for problems in the experimental process that may compromise the ability to use data to substantiate claims about phenomena of interest. What follows is one such set of tools that incorporates insights from philosophy of science, philosophy of experimentation and theoretical work in psychology and the social sciences.

The experimental process has discrete stages (Fig. 3.1). It is set in motion when an investigator or research team poses an empirical question about a phenomenon of interest. Examples of empirical questions in cognitive neuroscience may include: What area(s) of the brain are involved in attention? What kinds of information do dopamine neurons in the ventral striatum encode, represent, or process? What brain areas receive information from mirror neurons? Examples in cognitive neurobiology include: What is the role of protein kinase A in spatial memory? Is activation of cyclic-AMP response element binding protein necessary for long-term potentiation in area CA1 of the hippocampus in vivo? Are synaptic changes that accompany learning and memory similar to those that underlie addiction?

The phrase "phenomenon of interest" is intended to only very loosely capture the idea that *something* prompts an investigator to conduct an experiment – *some*

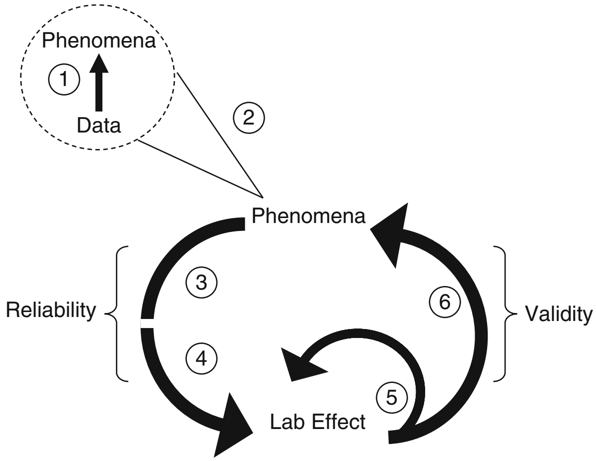

Fig. 3.1 The experimental process. (*1*) An investigator begins with an empirical question about a phenomenon of interest. This question is then redirected at an effect to be produced in the laboratory, thus initiating the (*3*) design and (*4*) implementation stages of data production. If the data production process is reliable, it results in the discrimination of one hypothesis from a set of competing hypotheses about the effect produced in the laboratory. This initiates the stage of data interpretation, in which the discriminated hypothesis is treated as a claim and is taken as true of (*5*) the effect produced in the laboratory and (*6*) the original phenomenon of interest in the world. If the claim was produced by a reliable data production process and it is true of the effect produced in the lab, it is valid (internal validity). If it was produced by a reliable data production process and it is true of the effect in the world, it is valid (external validity) (Sullivan 2009)

phenomenon of interest to him/her. One question that is relevant is how an investigator identifies, detects, or conceives of that phenomenon of interest. An obvious answer, if we look at modern neuroscience, is that in the history of cognitive neuroscience and cognitive neurobiology, some terms have been and continue to be widely deployed, although there is no consensus about how generally to define them. Despite such disagreements, constructs such as attention, working memory, face recognition, and spatial learning, are put forward as starting points for empirical inquiry – investigators pose questions that are directed at shedding light on at least as subset of those phenomena picked out by the concept. One question that remains, though, is how those phenomena that come to be designated by a general construct are identified or detected in the first place. One answer to this question is, if we consider cognitive phenomena more generally, that investigators notice changes in the behavior of organisms from some baseline, which serve as data points for their detection (Step 1 in Fig. 1). Bogen and Woodward (1988), for example, introduce a distinction between "data" and "phenomena" and commit themselves to the idea that phenomena are not observable, but only detectable by means of reference to data, which are observable. However, given that investigators begin experiments with questions about something that *is* detectable, whatever that phenomenon is, it is best understood as detectable derivatively, by means of reference to "data points." For example, most human beings (and non-human

animals) can recognize, after one or more encounters, the faces of conspecifics. This is something that can be detected by noting that on the second or third encounter with a face that was originally novel, an individual's behavior will reflect such recognition. Experiments in cognitive neuroscience and cognitive neurobiology may be said to have their original starting point in such changes in behaviors as exhibited by organisms "in the world." They may also begin with a phenomenon that has been detected by means of data points in the controlled environment of the laboratory (Step 2 in Fig. 3.1). There is most likely a complicated story that could be told as to how an investigator arrived at a particular empirical question. Teasing out this story – looking across review papers and conducting an historical study of the construct/phenomenon in question can be revealing when one attempts to assess the kinds of interpretive claims about a phenomenon that the data obtained from a given research study may be used to support (See, for example, Sullivan 2010).

The experimental process in neuroscience may be regarded as involving two stages: (1) *data production* and (2) *data interpretation* (Woodward 2000). Once an investigator poses an empirical question about a phenomenon of interest, the process of data production begins. Data production may be divided into two discrete stages: (1.1) *design* and (1.2) *implementation*.

The design stage, in basic terms, involves the development of an experimental design and protocol. An experimental design includes the overall set-up of the experiment, in so far as it specifies such things as the experimental context (e.g., how and where objects are to be arranged) and the materials and methods to be used. The experimental protocol is the set of step-by-step instructions that an investigator follows each time he or she runs an experiment. An experimental protocol essentially specifies how each individual experiment is to be run from start to finish. When an investigator is in the middle of an experiment and confused about what to do next – he or she will refer to the experimental protocol (not the experimental design).

Once an investigator has identified a phenomenon of interest, a way to produce that phenomenon of interest in the laboratory must be specified. The phenomenon, whether it is a cognitive function or a form of synaptic plasticity, must be operationally defined. An operational definition is built directly into the design of an experimental paradigm. An experimental paradigm is a standard method or procedure for producing an effect of a specific type. The following features are typically included in the design of experimental paradigms in cognitive neuroscience and cognitive neurobiology: (1) production procedures, namely, a specification of the stimuli (independent or input variables) to be presented, how those stimuli are to be arranged (e.g., spatially, temporally), and how many times they are to be presented during phases of (a) pre-training, (b) training, (c) post-training/testing; (2) measurement procedures that specify the response variables to be measured in the (a) pre-training and (b) post-training/testing phases of the experiment and how to measure them using apparatuses designed for such measurement; (3) detection procedures that specify what the comparative measurements of the response variables from the different phases of the experiment must equal in order to ascribe the cognitive function of interest to the organism, the locus of the function to a given brain area or neuronal population, or a plastic change to a synapse or set

of synapses. This detection procedure is simply an operational definition that specifies the measurable “change” in response variables that must be observed in order to say that the relevant phenomena have occurred.

Investigators in both cognitive neuroscience and cognitive neurobiology have freedom to design experiments – to vary the features of experimental paradigms in ways that they deem most appropriate for their explanatory aims. A “sub-protocol” is a production procedure, written up step-by-step, which corresponds to an experimental learning or electrophysiological stimulation paradigm. It will, for example, specify: (1) the duration of time of the presentation of each stimulus to be used in an experiment, (2) the duration of time that is to elapse between presentation of the stimuli used in an experiment, or the inter-stimulus interval (ISI), (3) the amount of time that is to elapse between individual trials, or the inter-trial interval (ITI), and (4) the amount of time that is to elapse before testing (or biochemical analysis). From the reader’s perspective, the multiplicity of experimental protocols and its implications (Sullivan 2009) are aspects of experimentation that we ought to be privy to when comparing results across different laboratories. This is because subtle changes in experimental paradigms and subprotocols may yield different and sometimes inconsistent results with respect to the phenomenon of interest, rendering it unclear which results should be taken seriously or how to fit the results into a coherent picture or model.

In cognitive neuroscience, the design stage also involves the selection of a subject population, a brain area of interest, experimental techniques (e.g., fMRI, EEG), and statistical analysis procedures (e.g., multivariate pattern analysis (MVPA)). In cognitive neurobiology, the design stage involves the selection of a model organism, a neuronal population or set of synapses, experimental technologies (electrophysiology, biochemistry, immunohistochemistry), and the statistical analysis procedure.

The design stage of data production typically proceeds in discrete stages: Questions are posed and suggestions about how to address them are provided; projections are then made about potential problems that might be encountered in the course of implementing the design and tentative solutions to these problems are offered; and finally, the combined considerations are worked into the design and protocol. Essentially, at this stage, the empirical question of interest is directed at some effect to be produced in the lab.

The implementation stage of data production (Step 4 in Fig. 3.1) begins at some point after an experimental design and protocol has been completed. It involves individual instantiations of the experimental design by means of the systematic following of the experimental protocol using the equipment, materials, and techniques assembled during the design stage. At this point, an investigator takes an individual subject or a group of subjects, and runs them through the steps of the protocol, following those steps as precisely as possible. The immediate output of each individual implementation of the design is an individual data point or set of data points.

Once enough data points for each type of experimental manipulation have been collected, the data points are combined and each complete data set is analyzed statistically. The statistically analyzed data is then used to discriminate one hypothesis from the set of competing hypotheses about the phenomenon of interest

produced in the laboratory. The process of data interpretation then begins. In the first phase of data interpretation (Step 5 in Fig. 1), the hypothesis discriminated by the data is taken as true with respect to the effect produced in the laboratory. That same claim may then be extended back to the original phenomenon of interest in the world that prompted the empirical question in the first place (Step 6 in Fig. 1).

Reliability and Validity

Individual researchers working in laboratories are interested in producing the data requisite to discriminate among competing (correlational, causal, or mechanistic) claims about a single phenomenon of interest. In the ideal case, they aim to design an experiment or set of experiments to produce a set of data *e* in order to adjudicate between a set of competing hypotheses, h_1, h_2, and h_3, about a phenomenon of interest. To do so, the evidence has to be adequate to this purpose. First, the data has to be the outcome of a reliable data production process. What does it mean for a data production process to be reliable? Mayo's (1991) "severity criterion" offers one understanding. In order for a test of a hypothesis to be reliable, it must pass a *severe* test – it must be *highly probable* that the data arising out of a test of a hypothesis would not yield evidence in support of that hypothesis if that hypothesis were in fact false. A related way of understanding reliability is that the process of producing data may be deemed *reliable* if and only if it results in statistically analyzed data that can be used to discriminate one hypothesis from a set of competing hypotheses about an effect produced in the laboratory (See also Bogen and Woodward 1988; Cartwright 1999; Franklin 1986, 1999; Mayo 1991, 1996, 2000; Woodward 1989, 2000). Reliability ought to operate as a constraint on the experimental process. When assessments are made about whether an experiment is reliable given the hypotheses it was designed to discriminate among, how the hypotheses are formulated is fundamental for assessing if the data may serve as adequate evidence.

A second desirable feature of the experimental process, which differs from reliability, is *validity*. Scientific accounts traditionally make use of a general notion of validity, which is taken to be a feature ascribed to experiments or tests. According to these accounts, an experiment is regarded as *valid* if it supports the conclusion that is drawn from its results (e.g., Campbell and Stanley 1963). Scientists and philosophers draw a distinction between external and internal validity (e.g., Cook and Campbell 1979; Guala 2003, 2005). Investigators not only wish to have the conclusions of their results apply to the effects under study in the laboratory (internal validity), they also hope that these conclusions apply to the phenomena of interest at which their empirical questions were originally directed (external validity).

For example, on Francesco Guala's account (2003, 2005), the *internal validity* of an experimental result is established when that result captures a causal relationship that operates in the context of the laboratory. That experimental result is *externally* valid when it captures a causal relationship that operates in "a set of circumstances of interest," outside the laboratory. However, validity may also be understood as a feature of interpretive claims rather than of experimental results. Whereas

experimental results are statistically analyzed sets of data, interpretive claims are what arises when a hypothesis that has been discriminated from a set of competing hypotheses by a set of data is taken as true of an effect produced in the laboratory as well as the original phenomenon of interest outside the laboratory. On this understanding of validity, an interpretive claim about an effect produced in a laboratory, is *internally* valid if and only if that claim is true about the effect produced in the laboratory. A claim about a phenomenon of interest outside the laboratory is *externally* valid if and only if that claim is true about that phenomenon.

One way to understand the relationship between reliability and validity is that they operate as normative constraints on the experimental process, yet give rise to conflicting prescriptions. Reliability prescribes simplifying measures in the context of the laboratory in order to narrow down a set of competing hypotheses about the effect produced in the laboratory. Insofar as it operates to constrain the process of data production, it inevitably restricts the extension of interpretive claims to the laboratory. Validity, however, pulls in the opposite direction. It prescribes that an investigator build into an experimental design those dimensions of complexity that accompany the phenomenon of interest in the world about which an investigator would like to say something. Adhering to the normative prescriptions of validity will inevitably lead to a decrease in the simplicity of the effect produced in the laboratory and an expansion of the set of competing hypotheses that pertain to that effect. In other words, it will lead to a decrease in reliability. However, without reliability, nothing is gained – for if control is lost in the laboratory, nothing true can even be said about the effect produced there – internal validity will be lost as well.

Although not represented explicitly in Fig. 3.1, it is relevant to mention two other types of validity that also may function as constraints on the experimental process. The first constraint is *ecological validity* (See, for example, Bronfenbrenner 1979; Schmuckler 2001). In contrast to external validity, which is concerned with whether an interpretive claim arrived at in a given study may be extended to the real world, ecological validity is concerned with whether the context, stimuli employed, and responses elicited in the experimental context are similar to those that would be found in the world. For example, performing a cognitive task in an fMRI scanner is different than engaging in a cognitive activity in a less restricted environment, so we might say that experiments using fMRI are not ecologically valid. The second type of validity that may constrain the experimental process is *construct validity* (See, for example, Cronbach and Meehl 1955; Shadish et al. 2002). The basic idea here is that investigators in cognitive neuroscience and cognitive neurobiology are interested in developing experimental paradigms that individuate specific cognitive capacities, because they want to be able to make structure-function or mechanistic claims about those capacities. This means that it ought to be the case that the effect under study in the laboratory is an actual instance of the phenomena picked out by a given construct (e.g., "attention"). Notice that if the constraint of construct validity is not met, this poses a problem for reliability – since an investigator may only use data to adjudicate between competing claims about a cognitive capacity produced in the laboratory if it is actually the case that the effect produced by means of an experimental paradigm is an actual instance of that capacity (See Sullivan 2010 for further discussion).

Failure to meet the criterion of construct validity should ideally prompt investigators to look for or develop an experimental paradigm that does a better job at individuating the capacity of interest.

Epistemic Challenges

The conceptual framework offered in the sections above entitled "The Experimental Process" and "Reliability and Validity" may be applied to research papers in cognitive neuroscience and cognitive neurobiology in order to illuminate the steps of the process and identify the various points that decisions are made or courses of action are taken that may impact the reliability of the data production process, the internal and external validity of the interpretive/correlational/causal claims made on the basis of the data, and ecological and construct validity. The framework may also serve as a basis for comparing the experimental process across research studies and determining what kind of interpretive claims are supported by a given body of data. Finally, using this conceptual framework as a backdrop, we can group together epistemic challenges for experimentation in cognitive neuroscience and cognitive neurobiology that have already been identified in the philosophical literature. This is the primary aim of this section.

For example, many philosophers have urged caution with respect to determining the kinds of structure-function claims that fMRI data may be used to support (e.g., Bechtel and Stufflebeam 2001; Bogen 2001, 2002; Delehanty 2007, 2010; Hardcastle and Stewart 2002; Klein 2010a, b; Mole et al. 2007; Roskies 2007, 2010; Uttal 2001, 2011, 2013; van Orden and Paap 1997). A common strategy is to identify the points in the data production process where techniques are used or decisions are made that may jeopardize or compromise the reliability of that process. If we begin by considering the design stage of data production, experiments using fMRI may be regarded as failing with respect to *ecological validity* in so far as subjects perform cognitive tasks that are designed to be implemented while a subject lies still and constrained inside the scanner. However, the cognitive activities that such experiments are supposed to shed light on the neural mechanisms of take place in far less restricted environments. Experiments using fMRI will thus always be limited when it comes to satisfying the criterion of ecological validity. Additionally, given that it is not clear that correlational claims about cognitive functions under study within the confined conditions of the laboratory may be extended beyond that context, fMRI experiments may also be regarded as lacking *external validity*. This does mean, however, that investigators learn nothing about "real-world" cognitive activities when they use fMRI. Rather, it means that we need to think carefully about what kinds of claims are supported by the data.[1]

[1]It is also relevant to note, that some investigators have sought to increase the ecological validity of fMRI experiments with innovative methods that allow for 3-D (as opposed to 2-D) objects to be used within the scanner (See Snow et al. 2011).

A third issue pertains to *construct validity*. For example, performing a face recognition task in a scanner with 2-dimensional stimuli presented on a flat-screen monitor is clearly different from being presented with real 3-D faces. This prompts the question of whether learning about face recognition with 2-D faces is revealing with respect to all of the phenomena that we typically identify as instances of facial recognition, which includes recognition of 3-D faces. A second and related issue, also having to do with construct validity, is whether an experimental paradigm used to study face recognition is sufficient for individuating the cognitive capacity it is intended to measure. For example, face recognition is a complex cognitive function that requires both attentional and mnemonic processes. Thus, an experimental paradigm implemented in an fMRI scanner ought to be able to differentiate the function of attending to faces from face recognition. Although cognitive neuroscientists emphasize the importance of task analysis as a means to ensure the construct validity of their experimental paradigms, they often disagree about which experimental paradigms are the best for measuring different cognitive functions. Such disagreements have prompted skeptics like Uttal (e.g., 2001) to argue that an objective taxonomy of cognitive functions will never be possible. However, some philosophers regard this as far too skeptical a conclusion (See, for example, Landreth and Richardson 2004).

The important point is that if concerns about ecological, external, and construct validity do not shape the development of an experimental design and experimental paradigm and protocol, this will likely impact the kinds of interpretive claims that are warranted by the data. In contrast, since hypotheses typically make reference to the cognitive capacity of interest, if the experimental paradigm is insufficient for individuating that discrete cognitive capacity, then the data will be unreliable for discriminating among competing hypothetical claims pertaining to that cognitive capacity.

Philosophical scrutiny has also been directed at the reliability of data production processes that involve the use of fMRI technology. For example, philosophers have pointed to the fact that the occurrence of the BOLD signal does not directly correlate with task-related neural activity, thus making it a potentially unreliable indicator of such activity (e.g., Bechtel and Stufflebeam 2001; Bogen 2001, 2002; Klein 2010a, b; Roskies 2007). Third, investigators are not always able to distinguish task-related effects from mere artifacts when looking at the raw data. Guesswork is typically required to improve the signal-to-noise ratio in data collected from each subject (i.e., within-subject data) and to eliminate artifacts (e.g., head motion during scanning) before processing the data. Such guesswork leaves open the possibility of experimenter error. Fourth, the fMRI data for each experimental condition has to be determined and averaged across subjects. This requires that the data be mapped and fitted onto an atlas of the brain (e.g., Talaraich atlas). Given differences in the shape and sizes of subjects' brains, averaging the data across subjects and fitting it into the atlas leaves open the possibility of data distortion. Another problem concerns the method of subtraction. In order to determine which area of the brain is involved in which cognitive task, investigators compare the BOLD signal observed on two task conditions that are thought to differ exclusively

with respect to one cognitive activity. For example, face recognition is thought to involve familiarity as well as recollection. One might thus imagine that a subject could be run in a face recognition paradigm and a familiarity paradigm and that activity observed in the familiarity paradigm could be subtracted from that in the face recognition paradigm to yield that area of the brain that is relevant for recognition. However, this method assumes that the two tasks actually discriminate between these two cognitive capacities, which may not be the case (For further discussion, see Bechtel and Stufflebeam (2001); Bogen (2001, 2002); Klein (2010a, b); Roskies (2007, 2010)).

A final issue with fMRI concerns what can be concluded on the basis of fMRI images. As several philosophers have argued, fMRI images are themselves outcomes of data interpretation rather than products of the data production process (e.g., Bogen 2002; Klein 2010b; Roskies 2007). Thus, conclusions that are made on the basis of these images – i.e., using the images themselves to adjudicate among competing hypotheses concerning structure-function relationships in the brain – will fail if decisions made during the stages of data processing involve the introduction of errors that fail to preserve the integrity of the raw data. This is one reason why philosophers have argued that analytic scrutiny must be directed at the analytical techniques involved in the production of fMRI images (e.g., Bogen 2002; Klein 2010b; Roskies 2010).

Despite the apparent limitations of fMRI technology, it continues to be widely used in cognitive neuroscience. Many neuroscientists, however, are aware and openly acknowledge these limitations and are in search of more reliable approaches to locating regions of the brain that subserve cognitive functions, identifying patterns of connectivity between different brain regions, and understanding the processing of information through the brain (See, for example, Logothetis 2008; Culham 2013 http://culhamlab.ssc.uwo.ca/fmri4newbies/).

Cognitive neurobiological experiments have also been a target of philosophical analysis. First, when it comes to the process of data production, cognitive neurobiologists have traditionally been concerned almost exclusively with reliability of the data production process and less concerned with issues of external, ecological, and construct validity. Given that investigators aim to establish causal relationships between cellular and molecular activity and behavior, in order to rule out the possibility of confounding variables, animal subjects are often raised in impoverished environments and trained with types of stimuli having parameters they would be unlikely to encounter in the real world (See Sullivan (2007; 2009) for further discussion). The dissimilarity between the laboratory and the external world thus jeopardizes the ability to extend causal claims established in the laboratory to real-world contexts (See Sullivan (2009) for further discussion).

Another issue that arises with respect to experiments in cognitive neurobiology is that not all investigators are concerned with construct validity. Many investigators are less interested in the cognitive processes that occur when an animal is trained in an experimental learning paradigm than with obtaining data that indicates that an observable change in behavior has occurred. Such data is then used as a basis

for inferring that the cognitive function that the paradigm purportedly individuates has been detected. However, sometimes it is unclear what cognitive capacity a given experimental paradigm actually individuates, which compromises the ability to use data collected using that paradigm as a basis for making causal claims about the role of cellular and molecular activity in a discrete cognitive function (See Sullivan (2010) for further discussion).

Philosophers have also addressed the question of whether results from experiments using model organisms, which are commonplace in low-level neuroscience and the neurobiology of learning and memory, are extendable to the human case (e.g., Ankeny 2001; Burian 1993; Schaffner 2001; Steel 2008; Sullivan 2009). Model organisms include, for example, rodents, sea mollusks, and fruit flies. These organisms are referred to as "models" in so far as scientists use them to establish causal relationships that they aim to generalize to the human population. However, differences between the two populations (i.e., laboratory animals and human beings) and the two contexts (lab versus ordinary environment) complicate the extrapolation of findings from the one context to the other. This prompts the question: When is the extrapolation of causal claims from the one context to the other warranted? Proponents of extrapolation, such as Daniel Steel (2008), have sought to provide an account that puts the investigative strategy on firmer epistemological footing. Of course, strategies for improving extrapolation from model organisms to the human case will vary depending upon the kinds of causal claims at issue (e.g., Sullivan 2009).

Conclusion

Philosophical work on the epistemology of experimentation in neuroscience, as is evident in the above examples, has been directed primarily at the knowledge-generating capacities of specific investigative strategies, tools, and techniques. However, neuroscience is a rapidly expanding field with global aims, the achievement of which requires the development of new and complex technologies. Ideally, we would like to have a workable set of analytic tools that we could apply in different areas of neuroscience and direct at different investigative strategies with the aim of determining whether those investigative strategies are knowledge-generating. Identifying one general set of conceptual tools has been the aim of this article.

Realization, Reduction, and Emergence: How Things Like Minds Relate to Things Like Brains

Abstract

Debates over reduction and emergence have raged in both philosophy and the sciences. Both sets of debates are surveyed to illustrate the ongoing discussions driven by the sciences and why they are rather different than philosophers commonly suppose. Unlike philosophical debates, scientists on both sides of their discussions accept that composition is universal in nature, that multiple realization exists, and that higher sciences are indispensable. The ongoing debates instead focus on the ontological structure of a certain kind of common case, including what entities are determinative and the varieties of determination.

Introduction

Lively debates rage in the sciences over reduction and emergence. On one side, there are scientific reductionists like Steven Weinberg or E.O. Wilson pressing increasingly sophisticated positions under the slogan that "Wholes are nothing but their parts" (Weinberg 1994, 2001; Wilson 1998). On the other side there are scientific emergentists such as Philip Anderson, Robert Laughlin, or Walter Freeman whose views can be sloganized as "Wholes are more than the sums of their parts" but also that "Parts behave differently in wholes" (Anderson 1972; Freeman 2000; Laughlin 2005). These scientific discussions utilize imprecise understandings of reduction and emergence and also of compositional relations, i.e., "parts" and "wholes," but connect directly to scientific explanations, concrete cases, and hence current empirical evidence.

Reduction and emergence have also been the focus of long-standing debates in philosophy. And there are now also philosophical accounts of scientific relations of composition such as the so-called realization between properties. In fact, on reduction, emergence, and composition, there are an array of competing philosophical frameworks that are very precise, but which are also often technical and inaccessible in character, and framed at some distance from concrete scientific cases and evidence. Although a potential resource, this array of philosophical machinery often makes it hard to see the wood for all the trees.

Given the state of contemporary debates, the primary goal of this survey is to provide the reader with an understanding of the bigger picture that will allow them to see what drives the debates, the nature of the competing positions, and why the issues between them may matter. Previous philosophical discussions of reduction and emergence have simply ignored scientific debates and their positions, but this exclusion looks unprincipled. This survey therefore engages both scientific and philosophical accounts. In fact, the approach here is to start with scientific phenomena and positions, since this reengages the core empirical evidence that plausibly generates the debates. However, the secondary goal of the survey is to provide the reader with an overview of the main philosophical frameworks on each topic.

Overall, the survey shows that the nature of the debates is rather different than philosophers have assumed with regard to both their deeper issues and live positions. Rather than following previous philosophical debates in battling over whether composition is universal in nature, multiple realization exists, or higher sciences are indispensable, for example, all the live positions in ongoing scientific debates over reduction and emergence now accept these claims. Instead, the debates in the sciences focus on disputes about the ontological structure of key scientific cases and disagree over the entities that are determinative, and the varieties of determination, in such examples.

Part 1 surveys the compositional notions posited in the key kind of mechanistic explanation in the sciences and reviews some of the philosophical frameworks used to articulate them. Using this platform, Part 2 highlights how scientifically based forms of *ontological* reduction are live positions that avoid the famous philosophical objections that work against the *semantic* reduction championed by

the Positivists. Lastly, Part 3 distinguishes various notions of emergence, considers whether they challenge such a reductionism in the sciences, and highlights one form of emergentism that does so. Overall, the survey consequently highlights the shape of ongoing debates over reduction and emergence in the sciences.

Part 1: Mechanistic Explanation and the Nature of Compositional Relations

Scientific reductionists and emergentists all focus on what can be termed "inter-level mechanistic explanations" which explain some higher-level entity using lower-level entities taken to compose it. To illustrate the features of these explanations, and their compositional concepts, consider the current scientific account of the growth of dendritic spines in neurons whose basis is familiar from the explanations of cellular motility.

Putting aside all kinds of messenger and other proteins, and a lot of complexities, dendritic spines grow through the polymerization of G-actin (see Fig. 4.1). Multiple G-actin filaments polymerize in certain directions, pressing against other molecules embedded in the cell membrane, thereby reshaping the cell. In this account, scientists postulate a number of compositional relations. There are *part-whole* relations between individuals, since various molecules are taken to be parts of the neuron. There are *realization* relations between property instances, because various properties of molecules result in a property of the neuron. Finally, there is the *implementation* of processes, since the neuron's process of growing a dendritic spine is composed by processes of actin polymerization.

These compositional relations between different categories of entity all share characteristics. Such relations contrast with causal relations, since (i) composition is a species of *noncausal determination relation* that is not identical to the triggering and manifestation of powers, is synchronous, involves entities that are not wholly distinct (i.e., are in some sense the same), and does not involve the transfer of energy and/or mediation of force. (ii) Compositional relations are plausibly *asymmetric*, *irreflexive*, and *transitive*. (iii) Scientific composition also always involves "teams" of individuals, which bear spatiotemporal, productive, and/or powerful relations to each other and are spatially contained within the individual associated with the composed entity. Consequently, (iv) such composition relations are a species of *many-one relation* with teams of many components, whether individuals, property/relation instances, or processes, and one composed entity. (v) Compositional relations have *qualitatively distinct relata* and hence involve "qualitative" emergence, because composed individuals always have different powers and properties, hence grounding different processes, than the powers, properties, and processes found in their components. Thus the cell has the property of growing spines and the powers and processes associated with it, while G-actin has no such properties, powers, or processes. (vi) Scientific composition is plausibly a species of *natural necessitation* where at a time (or across some duration of time in the case of the implementation of processes), the components suffice for the

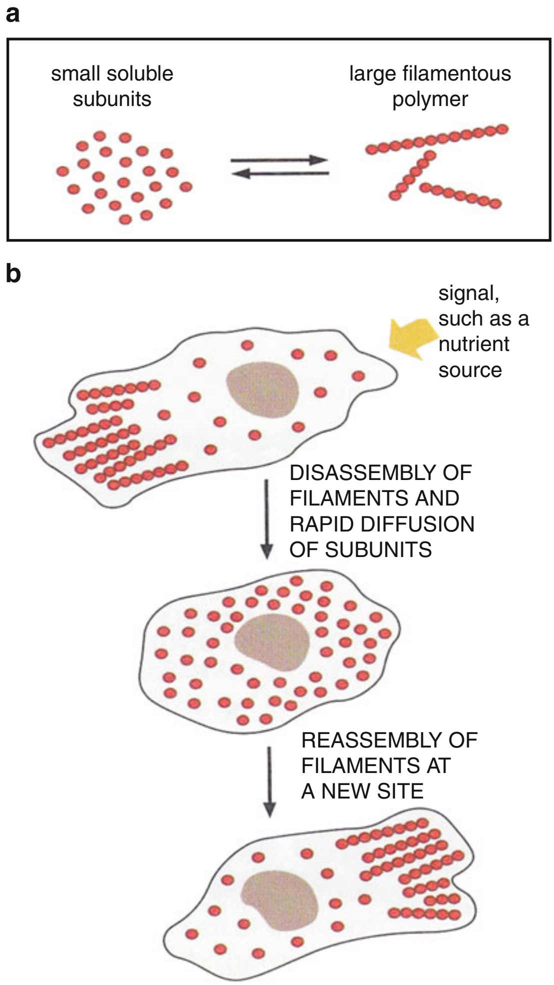

Fig. 4.1 Diagram of the mechanism underlying cell motility and, in the last two steps, the growth of dendritic spines (From Alberts et al (2007), p. 971)

composed entity under the relevant conditions. Thus, when there are certain proteins, with specific relations, under the relevant conditions, there must be the cell. And (vii) scientific composition relations always hold under certain background conditions.

These few characteristics suggest inter-level mechanistic explanations work by representing compositional relations between entities. For, as was just illustrated in (vi), composition is plausibly a species of natural necessitation. Consequently, in an inter-level mechanistic explanation, the lower-level entities of the explanans necessitate, through their compositional relations, that the entities of the explanandum exist under the relevant conditions. Hence the explanans of an inter-level mechanistic explanation plausibly explains its explanandum.

Philosophical attempts to more precisely articulate the nature of scientific notions of composition constitute a very lively area of ongoing research. In the 1980s, philosophers sought to use species of "supervenience" to understand scientific composition. Basically, supervenience is a relation of necessary covariation between entities. The kinds of supervenience thus differ in their relata and the strength of necessity that holds between them. From the 1990s onwards, however, philosophers have rejected supervenience as an account of composition, since supervenience allows covarying entities that are wholly distinct, whereas the relata of compositional relations are in some sense the same (Horgan 1993). [Recall condition (i)].

Many philosophers interested in scientific composition have subsequently shifted their attention from supervenience to so-called realization relations between property instances, so the compositional relations between individuals and processes have been comparatively neglected. Plausibly taking their inspiration from scientific explanations, the two popular kinds of account of realization focus on the differing versions of the idea that components do the causal "work," or as it is often put "play the causal role," of the composed entity.

"Flat" or "subset" views of realization are most popular (Kim 1998; Wilson 1999; Shoemaker 2001). These views take realization to involve causal role-playing through overlap of powers because the realized property instance is individuated by a subset of the powers of the realizer instance. So when one has the powers of the realizer, one must also have the individuative powers of the realized property and hence have a realized instance as well. Realization is thus taken to be a one-one relation of properties of the same individual that overlap in powers and hence overlap in causal role or "work."

One objection to the flat/subset view is that in inter-level mechanistic explanations, such as the example of dendritic spine growth above, realization is apparently a many-one relation between property instances of distinct individuals and has qualitatively different relata that do not share powers (Gillett 2002). These difficulties have prompted alternative, "dimensioned" accounts of realization positing a team of property instances, of component individuals, that realize another qualitatively distinct property instance, of a composed individual, with which they share no powers (Gillett 2002, 2007 and possibly Shoemaker 2007). Here the idea is that many realizer instances can together jointly fill the role of a realized property. Dimensioned views are thus claimed to better fit the features of the relations posited in real scientific explanations.

To summarize, mechanistic explanations often posit compositional relations between the entities found at different levels and studied by different sciences. Such compositional relations are a species of noncausal, synchronous, natural necessitation where, at a time and under the relevant conditions, the component entities suffice for the composed entity because the "work" of the components results in the "work" of the composed entity, whether through role-playing by overlap or joint role-filling. With these points in hand, one can now better appreciate what drives reductionism and emergentism about the sciences.

Part 2: Ontological Versus Semantic Reductionism in Science and Philosophy

It is important to note a common usage of "reductionist" to mean anyone seeking inter-level mechanistic explanations. However, both sides in scientific and philosophical disputes over reduction and emergence now accept the need to search for inter-level mechanistic explanations. So, under the common usage, *everyone* is a "reductionist"! The common usage thus unhelpfully slides over substantive differences between the parties, so it is better to use "everyday reductionism" to refer to the search for inter-level mechanistic explanation.

Scientists like Weinberg or Wilson claim that the results of everyday reductionism lead to more substantive conclusions regarding what may be termed "scientific reductionism." The evolutionary biologist George Williams summarizes the scientific reductionist's key contention when he tells us that the nature of inter-level mechanistic explanation allows us to understand "complex systems entirely in what is known of their components parts and processes" (Williams 1985, p. 1). That is, wherever there are inter-level mechanistic explanations of certain higher-level entities, i.e., certain "wholes," through lower-level component entities, i.e., "parts," then scientific reductionists claims that the composed entities are "nothing more than," "nothing over and above," or "nothing but" such components (which include component individuals and their properties and relations to each other) which should be taken to be the only determinative entities, i.e., the only entities that make a difference to the powers of individuals.

Scientific reductionists thus press ontological parsimony arguments using the compositional notions posited in inter-level mechanistic explanation. There are two hypotheses about the determinative entities underlying such explanations. First, there is the usual hypothesis that there are *both* determinative composed *and* component entities. But the scientific reductionist's rival hypothesis is that there are *only* determinative component entities. For the reductionist notes that when there are compositional relations, then components, under the relevant conditions, suffice for the "work" of the composed entity. Consequently, the reductionist claims that their hypothesis can account for the "work" of both composed and component entities. But, claims the reductionist, that means the hypothesis that there are only determinative component entities is equal in its explanatory adequacy to the hypothesis that there are both determinative component and composed entities. And the parsimony principle tells us that when there are hypotheses that are equally explanatorily adequate, then only the simpler of these hypotheses should be accepted. The scientific reductionist thus concludes that for any successful inter-level mechanistic explanation, it should only be accepted that component entities are determinative. If the Eleatic principle is also endorsed that says the only entities that exist are those that are determinative and make a difference to the powers of individual, then the reductionist will conclude that only the existence of component entities should be accepted.

The result is a form of *ontological reductionism*, for a commitment to both determinative composed and component entities has been reduced to a commitment

only to determinative component entities. And scientific reductionists consequently press connected claims about laws and many argue that, ultimately, the only determinative laws of the universe are the laws of physics focused on the basic component entities (Weinberg 2001, p. 115; and Wilson 1998, p. 55).

However, scientific reductionists also emphasize what Weinberg (1994, p. 52) terms the "compromising" nature of their position, since they accept that higher sciences are in principle indispensable for expressing various truths, including true explanations and laws. For example, Weinberg tells us that:

> The study of statistical mechanics, the behavior of large numbers of particles, ... is a separate science because when you deal with very large numbers of particles, new phenomena emerge ... even if you tried the reductionist approach and plotted out the motion of each molecule in a glass of water using the equations of molecular physics ..., nowhere in the mountain of computer tape you produced would you find the things that interested you about water, things like turbulence, or temperature, or entropy. Each science deals with nature on its own terms because each science finds something in nature that is interesting. (Weinberg 2001, p. 40)

As this passage illustrates, scientific reductionists like Weinberg accept that components form powerful relations to each other bringing into existence new collectives of components, hence new phenomena emerge and so too do new levels understood as scales of such collectives of components. Scientific reductionists like Weinberg thus take higher sciences and their predicates to be indispensable for expressing truths about such collectives of components (Gillett 2007, forthcoming).

Scientific reductionism is consequently an ontological reductionism combined with a species of semantic *anti*-reductionism. Thus in a successful inter-level mechanistic explanation of a neuron using molecules, or of our psychological properties using neuronal or molecular components, the scientific reductionist contends that only the molecules or neurons are determinative or even exist. But the reductionist also accepts that there are many true explanations, or laws, that can only be expressed using the predicates of higher sciences, like "neuron" or "believing," which they take to refer to collectives of such components. Scientific reductionism is thus distinctive by:

(a) Accepting the central role in the sciences of inter-level mechanistic explanations and their compositional concepts
(b) Pressing an ontological form of reduction, driven by parsimony arguments focused on compositional concepts, under which only components are determinative or exist and where the only determinative laws are those holding of components
(c) Accepting the in principle indispensability of higher sciences and hence endorsing semantic anti-reductionism
(d) Embracing a complex macro-world in collectives of components where there is qualitative emergence and "More is different."

Listing these features usefully highlights the contrasts with the Positivists' account of "reduction" that continues to configure philosophical discussions.

Abandoning metaphysics, the Positivists famously needed accounts of explanation and reduction not involving metaphysical concepts like the compositional ones

used in inter-level mechanistic explanations. Instead, the Positivists ultimately fixed upon s*emantic* accounts. For example, the Positivists' view of explanation is the "deductive-nomological" or "DN" model (Hempel 1965) that takes all scientific explanations to have the form of deductive arguments explaining a statement describing the phenomena by deriving it from a law statement serving as one of the premises of such an argument. The Positivist account of explanation thus leaves no room for inter-level mechanistic explanations that often do not utilize derivational relations or laws.

The Positivists' account of reduction, in "semantic" or "Nagelian" reduction (Nagel 1961), builds on the DN account of explanation by focusing on the derivation of the law statements of the theories of higher sciences from the law statements of lower sciences in combination with identity statements relating the predicates of the relevant higher and lower sciences. Under their DN account of explanation, such derivations of higher-level laws constituted an explanation of them and thus semantic reduction putatively "reduced" higher-level laws, and associated theories and sciences, to lower-level laws, theories, and sciences.

Nagelian reduction thus plausibly entails that higher sciences are dispensable, at least in principle, and hence that lower sciences can perform all the significant work of the sciences. In addition, the use in Nagelian reduction of identity statements relating the predicates of different sciences implies that all properties of the higher sciences are coextensive with properties of lower sciences and that there is only one level in that of the micro-world of components. In contrast to scientific reductionism, Nagelian reduction thus:

(a) Uses an account of scientific explanation, in the DN view, that excludes many inter-level mechanistic explanations
(b) Pursues a semantic form of reduction focusing on the reduction of higher-level law statements to lower-level statements
(c) Entails that higher sciences are dispensable and lower sciences are semantically omnipotent, hence endorsing a thorough-going semantic reductionism
(d) Implies, through its inter-level identities, that there are no macro-levels in nature

It can quickly be appreciated why it is important to understand both scientific reductionism and Nagelian reduction, and the differences between them, by looking at the famous philosophical critiques of "reduction."

In the 1970s and 1980s, philosophers of science like Hilary Putnam and Jerry Fodor used examples of inter-level mechanistic explanation to argue that there are few reductions as understood by the Positivist account (Putnam 1967; Fodor 1974). Most famously, the so-called "Multiple Realization Argument" was built around the fact that many scientific properties are "multiply realized" by a variety of distinct lower-level properties and hence not coextensive with such properties, thus blocking inter-level identities and the widespread existence of Nagelian reductions. In addition, the "Predicate Indispensability Argument" argued that, in such cases of multiple realization, the predicates of lower sciences often only serve to express the heterogeneity of lower-level properties, thus missing the true explanations concerning the homogeneities at higher level that can only be expressed using

predicates of higher sciences. Consequently, higher sciences were taken to be indispensable and semantic reduction was challenged in another way.

These famous objections are still widely taken by philosophers to show that reductions are unavailable and that reductionism is a dead view. But the underlying assumption is that reduction must be Nagelian reduction and this can now be seen to be a very dangerous assumption. Neither the Multiple Realization Argument nor the Predicate Indispensability Argument plausibly applies to scientific reductionism that actually accepts their conclusions. For scientific reductionism eschews identities and can use multiple realization to drive its parsimony arguments, thus agreeing with the Multiple Realization Argument's conclusion. And scientific reductionism consequently defends the indispensability of higher sciences, hence accepting the conclusion of the Predicate Indispensability Argument.

Scientific reductionism thus teaches us that semantic and ontological forms of reduction need to be carefully separated. And this highlights the importance of recent philosophical work on ontological forms of reduction that plausibly presses similar lessons. Most prominently, Jaegwon Kim (1998) has formulated an ontological model of reduction in his "functionalization" account, and other versions of ontological reductionism have been offered by philosophers of science such as Alexander Rosenberg (2006) and philosophers of mind like John Heil (2003). In addition, Kim's famous arguments about the "problem of mental causation" are similar in their conclusions to the scientific reductionists' parsimony arguments. [See his "Causal Exclusion Argument" (Kim 1993) and "Supervenience Argument" (Kim 1998).]

There are differences between them, but these philosophical and scientific accounts of ontological reductionism can plausibly inform and strengthen each other. The wider points that consequently come into view are as follows: First, there are substantive forms of ontological reductionism driven by inter-level mechanistic explanations and their compositional concepts such as the realization between properties. And, second, the standard objections to reduction only work against Nagelian reduction and leave such a scientifically based ontological reductionism untouched. Contrary to the received philosophical wisdom, and far from being dead, ontological reductionism thus offers live hypotheses about the structure of cases of inter-level mechanistic explanation in the neurosciences and beyond.

Part 3: The Varieties of Emergentism

Though the famous philosophical objections to "reduction" fail to critically engage a scientifically based reductionism, many self-proclaimed "emergentists" have sought to do so. However, discussions of emergence notoriously involve distinct notions of emergence that are too rarely distinguished. This section therefore starts by outlining four of these concepts and assessing whether any of them poses a challenge to scientific reductionism.

The qualitative emergence that goes along with compositional relations was noted earlier. A qualitatively emergent property is a property of a composed individual that is not had by any of its component individuals. Many writers point

to qualitative emergence as significant evidence against reductionism, but this is a mistake when discussing scientific reductionism. For qualitative emergence accompanies the scientific composition that actually drives the parsimony arguments of scientific reductionism.

Scientific work on complex systems has brought what is termed "weak" emergence to prominence (Bedau 1997). A weakly emergent property is a realized property of a higher-level individual for which the higher-level theories and/or explanations about this property cannot be derived from, or dispensed with in favor of, theories and/or explanations concerning realizer properties. Once again, weak emergence has often been taken to block reduction and this is plausibly true for semantic reduction since the required derivation and dispensability are unavailable. However, weak emergence is compatible with scientific reductionism which requires no derivational relations to run its parsimony argument and accepts the indispensability of higher sciences for expressing many truths about nature.

Rather different is "ontological" emergence, for an ontologically emergent property is instantiated by a higher-level individual but is not realized by other properties (O'Connor 1994). The existence of ontological emergence is often characterized by philosophers as being at the heart of debates over reduction – thus making the central issue the existence of uncomposed entities at higher levels in nature. However, it is quickly seen that this misses what is at issue in scientific debates. It is true that the reductionist's parsimony arguments do not apply to ontologically emergent properties because they have no realizers. However, for similar reasons, ontological emergence also does not block the scientific reductionist's arguments that focus on cases where there are inter-level mechanistic explanations that provide qualitative accounts of the components of the relevant higher-level entities including properties. For ontological emergence consequently does not exist in such cases of successful mechanistic explanation, since all the relevant entities, including properties, are composed. Arguments about the implications of ontological emergence therefore leave untouched the core arguments of scientific reductionism about the implications of mechanistic explanations.

A final notion of emergence has been widely rejected by philosophers and scientific reductionists alike. This is "strong" emergence in a realized property instance that is *both* realized *and* determinative – just the combination of features that the scientific reductionists' parsimony argument, or Kim's reasoning, suggests should never be accepted together. However, scientific emergentists have used real examples to defend a species of strong emergence that appears to offer important challenges to a scientifically based ontological reductionism and its arguments.

For example, system biologists defend this kind of emergence about the molecular components of cells (Boogerd et al. 2005), but it is more appropriate here to focus on an instance from the neurosciences. For example, with regard to "emergence" Walter Freeman claims:

> An elementary example is the self-organization of a neural population by its component neurons. The neuropil in each area of cortex contains millions of neurons interacting by synaptic transmission. The density of action is low, diffuse and widespread. Under the impact of sensory stimulation, by the release from other parts of the brain of neuromodulatory chemicals... all the neurons come together and form a mesoscopic

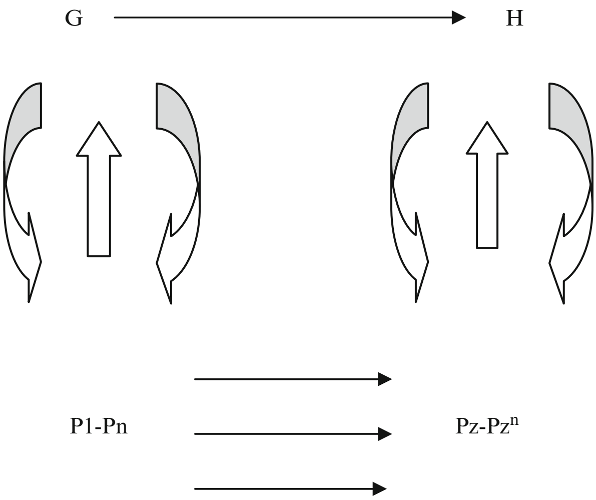

Fig. 4.2 The structure of determinative relations that scientific emergentists claim exist in some cases of inter-level mechanistic explanation. The strongly emergent property instance G is realized (*upward vertical arrow*) by the properties P1-Pn, but G exerts a novel species of determination (*curved downward arrows*) on the powers contributed by these realizers

> pattern of activity. This pattern simultaneously constrains the activities of the neurons that support it. The microscopic activity flows in one direction, upward in the hierarchy, and simultaneously the macroscopic activity flows in the other direction, downward. (Freeman 2000, pp. 131–132)

Let us unpack the interlinked claims in the passage and the position it describes. First, there are no uncomposed entities at the higher level, since the neural population is completely composed. Second, the existence of emergence is not based upon ignorance, but putatively derives from a detailed quantitative understanding of the behavior of components. For, third, writers like Freeman claim that it is now known that components sometimes contribute different powers, and hence behave differently, under the condition of composing a certain higher-level entity where these components would not contribute such powers if the laws applying in simpler aggregations exhausted the laws applying in the complex aggregation. Let us call such powers contributed by a component *differential powers*. Fourth, scientific emergentists like Freeman claim that the differential powers of components are best explained as being determined by the "emergent" entities they compose where this is a novel species of noncausal, but also non-compositional, determination. Lastly, the scientific emergentist claims that new laws about components hold in such circumstances and refer to the composed entity, thus disputing the view of the determinative laws offered by the reductionist.

All manner of issues and questions arise about such claims, but their potential significance for strong emergence is clear. In such circumstances, a realizer property instance, such as a property of a neuron, only contributes certain differential powers when realizing a certain higher scientific property such as one had by a neural population. Scientific emergentists like Freeman take the *realized instance*, the composed entity, to determine the differential powers of their realizers, i.e., their components. At a time, there are thus both the upward and downward determination relations outlined in Fig. 4.2. But when "Parts behave differently in wholes" in this manner,

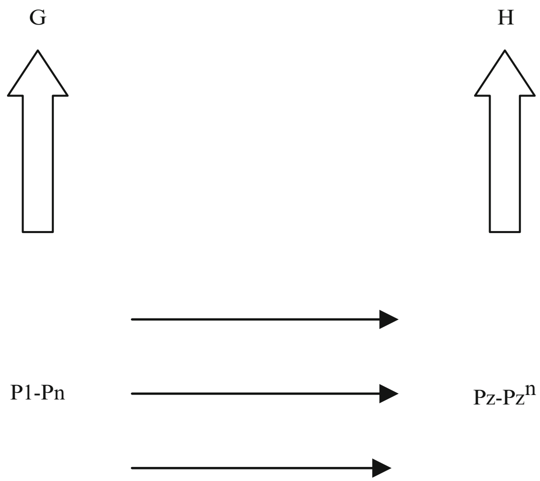

Fig. 4.3 The determinative structure of all cases of composition assumed by scientific and philosophical reductionists. At a time, there are only upward compositional relation between the realizers P1-Pn and the realized property G

then there is an overlooked way, or set of ways, to potentially defend the further claim that "Wholes are more than the sum of their parts." For realized instances, the composed entities, determine some of the powers contributed by their realizers, as well as contributing their own powers, and it appears that there is thus strong emergence in these property instances that are both realized and also determinative.

Unsurprisingly, this kind of scientific emergentism challenges the parsimony arguments of the scientific reductionist or reasoning like Kim's. The scientific emergentist contends that reductionist arguments wrongly assume all cases of composition must have the character outlined in Fig. 4.3 with determinative relations only going upwards at a time. However, if the scientific emergentist's cases are actual, or even possible, then the reductionist reasoning overlooks the different kind of situation outlined in Fig. 4.2. In such cases of strong emergence, it is true that there are compositional relations going upwards, but also true that composed entities are downwardly determinative as well. If its claims can be sustained, scientific emergentism would thus challenge the *validity* of the scientific reductionist's parsimony arguments.

Philosophers, sometimes working together with scientists, have offered theoretical frameworks seeking to articulate this kind of scientific emergentism and its implications (Boogerd et al. 2005; Gillett forthcoming; Mitchell 2009). The resulting forms of scientific emergentism plausibly offer live hypotheses about successful cases of inter-level mechanistic explanation in the sciences that are important competitors to those of scientific reductionism.

Conclusion

This survey illustrates the substantive, ongoing debates in the sciences and philosophy over reduction and emergence. Earlier philosophical debates fought over the

ubiquity of mechanistic explanation or whether compositional concepts apply to all entities and over whether multiple realization exists or higher sciences are dispensable. However, all the live positions in the present debates in the sciences now accept such claims. Scientific emergentism endorses the prevalence of mechanistic explanations and takes all higher-level entities to be composed. While scientific reductionism accepts that higher sciences are indispensable and that multiple realization exists. Ongoing debates about reduction and emergence, apparently tracking empirical evidence, have thus moved on from whether mechanistic explanations *exist* for all the entities in nature to focus on the *implications* of such explanations.

On one side, proponents of a scientifically based ontological reductionism claim that components like neurons, or even molecular constituents, are the only determinative entities in the cases of inter-level mechanistic explanation common throughout the neurosciences and that the productive interactions of such components are the only species of determination in such examples. While on the other side, scientific emergentists contend that components such as neurons, or even molecular entities, sometimes have differential powers and that emergent composed entities, whether populations of neurons, brains, or even psychological entities, downwardly determine that component entities have such powers – hence defending more determinative entities, and species of determination, than the reductionist.

The opposing scientific reductionist and emergentist views thus offer substantively different accounts of the structure of concrete scientific examples in the neurosciences and other sciences. And how the debates over these views are resolved will plausibly decide whether composed entities, like neurons, brains, or even ourselves, are taken to play a determinative role in the universe or whether the scientific reductionist's simpler picture of nature should be accepted.

Mental Causation

Abstract

The problem of mental causation in contemporary philosophy of mind concerns the possibility of holding two different views that are in apparent tension. The first is physicalism, the view that there is nothing more to the world than the physical. The second is that the mental has genuine causal efficacy in a way that does not reduce to pure physical particle-bumping. This chapter provides a historical background to this question, with focus on Davidson's anomalous monism and Kim's causal exclusion problem. Reponses to casual exclusion are categorized in terms of six different argumentative strategies. In conclusion, caution is advised regarding the inclination to reduce the mental to the physical and a positive direction is sketched for substantively characterizing mental causation by recourse to well-confirmed accounts of causation coupled with empirical research.

Introduction

Cognitive neuroscience is often taken to either imply, or minimally to be compatible with, a view about the nature of mind called physicalism. Physicalism is the view that everything in the world, including but not limited to the mind, is purely physical in character; it essentially denies the existence of nonphysical entities or processes. The debate about the existence and nature of mental causation stems from a tension between a commitment to physicalism concerning the nature of the mind, and the apparent causal efficacy of such mental events or states such as having an intention or committing an action. The commitment to physicalism is inconsistent with "spooky" mental causes, such that thoughts, beliefs, or intentions are not themselves physical, but somehow reach out and poke the physical world. Physicalism is generally taken to imply that, whatever mindedness turns out to be, it should fit clearly into the nexus of physical causes with which we are already familiar. On one hand, this commitment appears very much in line with the approach to studying the mind in cognitive neuroscience. On the other hand, the realm of the mental appears at least prima facie to be genuinely causally efficacious – we do at least *seem* to bring about our actions by deliberation and intentions on which we act – in ways that cannot be straightforwardly reduced to familiar physical causation. This perceived conflict between physical causation and the place of the mental is the source of debate about the existence and nature of mental causation.

The fact that the mental is characteristically ordered by rational norms that do not appear to exist in physical causation pulls toward causal autonomy of the mental from the physical, while the commitment to physicalism resists this as spooky or mysterious. Solving the problem of mental causation requires finding a way to reconcile physicalism about the mind with causal efficacy of the mental, either by situating mental causes in the physical world, by rejecting mental causes, or by rejecting physicalism. This chapter will focus on the first two of these options, since the commitment to physicalism is both widespread in this discussion, and a unifying premise shared by many disparate views.

The problem of mental causation is closely related to, but not the same as, what is often called the mind-body problem. The mind-body problem concerns the relationship between the mind and the body: Is the mind nothing more than the physical body with a certain arrangement of parts? Is the mind a collection of causal functions performed by the body? How does consciousness arise from the body? The problem of mental causation is intricately connected in that many answers to the question of how the mind and body are related will have starkly differing consequences for whether or not the mind has any genuine causal efficacy on the body, or on the world via the body. They are, however, different issues. The question of phenomenal consciousness and its relationship to various neurophysiological processes may be answered, for instance, without thereby yielding a firm answer to the question of whether phenomenal consciousness has genuine causal efficacy, on what it can act, etc.

Historical Background

The original version of the problem of mental causation as it figures in contemporary debates is often taken to begin with Descartes' Meditations (1641/1996), although it can be dated back as far as Plato's *Phaedo*. Descartes presented a dualist picture of the world as comprised of two distinct substances, physical and mental. Physical substances, or objects made of matter, are spatially extended and located, and are not capable of thought. Anything composed solely of matter moves via mechanical forces only; Descartes thought that animals, for instance, were simply very complicated automata. Mental substances, or minds or souls, are that which thinks; they are not spatially extended or located. Properties of physical substances are, on Descartes' view, fundamentally incompatible with mental substances. Minds cannot have shapes or motion, and material objects cannot have thoughts or sensations.

Humans are, according to Descartes, an intimate union of a material body that moves like a machine with a mental substance that thinks, that senses via the material body, and that can influence the motion of that material body. Descartes was careful to avoid a view in which the mind and body were overly separate. The mind-body union is not like the ship in which a sailor directs the motion, he says. A sailor can only know that there is damage to the ship's hull by going and inspecting it. But we can know things about our body in a direct way, by sensing, in a way that we cannot with any other material body to which our thinking minds are not intimately connected. We do not control our body in the distant way in which we control a puppet; there is an immediacy to how we move our limbs that is the consequence of our minds being connected in this special way to our body and not to other pieces of matter.

Descartes thus denies physicalism about the mind-body relationship: The mind could not be made out of particular bits of matter; no amount or organization of matter could ever comprise a mind, because it would always be of the wrong kind of substance to do so. But the mind is intimately connected to some particular chunk of matter, to its body. It receives sensations from that body and, most relevant for our purposes, it also moves that body directly, but no other bodies directly. There are then two directions of influence that pose a problem: How does the physical world have a causal effect on the mind via perception? And, how does the mind influence the body?

Descartes' account is illuminating of the trajectory of discourse on mental causation not only because he runs into a certain kind of problem, but also because he then proposes a certain kind of solution that runs into another very characteristic problem. His dualist account generates a clear case of a problem for mental causation by conceiving of the mind as an entirely different kind of thing than the physical body on which it acts. If physical motion is entirely mechanical, and the mind is entirely unphysical, how does the mind communicate motion to the body? His solution is to propose a way-station where physical bumpings and pullings are translated into signals that influence the mind. Sensation involves physical causation that is transmitted via a complicated series of physical machinery to a special

place in the brain – famously, he proposed the pineal gland as a possible site for this – that translates the physical signal into a mental one. Once the mind resolves to do something, such as lift an arm, that mental signal is then translated back via the same site to a physical signal that would pull and push on the right parts of the body to make the arm go up.

This solution to how the mind and body causally influence one another does not really solve the problem, though. Instead, it relocates it. Proposing a way-station that translates mental and physical influence back and forth between the two kinds of substance physically isolates the location whereby the mind controls the body, but still does not answer the problem of *how*, exactly, the pineal gland translates between two fundamentally different substances. Localizing the physical space in which such a translation happens is arguably an improvement over allowing it to happen all over the body, but still it does not budge the problem of mental causation: How does that mental influence get to the body, and use that body to influence the world? This has been called by Robb and Heil (2013) a problem concerning the causal nexus by which mind and body are connected: "Any causal relation requires a *nexus*, some interface by means of which cause and effect are connected."

The way in which this problem arises in Descartes' account is particular to his dualist views, and the problem of how the mind could exercise a causal influence in the physical world looks somewhat different when one rejects substance dualism. But it is a problem for causation that will arise in a different form anytime the mental and physical are treated as of different sorts: *How*, not merely *where*, does one causally influence the other?

This problem of how the mental could influence the physical simply does not arise in accounts of the mind that treat it as identical with, or at least of the same kind of metaphysical substance as, the brain – in other words, in any physicalist account of mind. In the twentieth century, for instance, the identity theory held that the mind just is the brain – processes in the mind are not merely correlated with, but simply are identical to, processes in the brain (for instance, Smart 1959). In this account, there is no causal influence of the mental beyond that of the causal influence exerted by the brain. Type identity theory is the view that types of mental processes, like pain, simply are types of physical processes, like C-fibers firing. The view that types of mental processes or events are nothing other than types of physical events or processes is also called reductive physicalism: physicalism, because it holds that the mind is physical in character, and reductive, because it holds that the mental reduces to the physical.

While there are different versions of it, reductive physicalism, in any form, solves the tension between a physicalist view of mind and the apparent causal efficacy of the mental by denying that mental causal efficacy is anything other than the causal efficacy of neurophysiological processes. The reductive element of the view means that mental causation is a placeholder for the real causal story which inevitably involves brain processes, microphysical particle states, or some other straightforwardly physical cause. Reductive physicalism about the mind follows a trend in the twentieth century that characterizes many scientifically informed philosophical accounts. It organizes the relationship between types like the mental

and physical in terms of levels, such that the causal efficacy (and, indeed, other features like metaphysical fundamentality) of higher levels depends on and reduces to that of lower levels. The mental is causally efficacious only insofar as it reduces to the physical, and the physical is causally efficacious. Reductive physicalists allow that mental terms are a pragmatic convenience and do not need to be eliminated, so long as they are understood as a kind of short-hand for the "real" causal story. This means that reductive physicalism is less strong than eliminative physicalism, which holds that mental terms will, or at least should, be replaced entirely (P.S. Churchland 1986; P.M. Churchland 1981).

Anomalous Monism and Causal Exclusion

The tension between physicalism and the causal efficacy of the mental was given an influential analysis by Donald Davidson (1980/2001), (1995). He aimed to both preserve physicalism as a view about the nature of the mind as part of the physical world studied by science, while also arguing for autonomy from physical causation for causes and causal relations that involve mental terms. The mental was part of the physical world, but could not be reduced to the laws of physics. His view, anomalous monism, was pitched at least partially as an alternative to reductive physicalism. His account offers a nonreductive physicalist way to accommodate both of the intuitions that there is nothing nonmaterial about mental events and that mental events do have genuine causal efficacy.

This section explores Davidson's account and Kim's challenge to it, and how this sets the framework for much of the contemporary debate about mental causation, as well as connecting that debate to the broader issue of higher versus lower level causation generally.

Davidson subscribes to what he calls the Cause Law thesis (1995), which is one of the key premises in his account and closely related to the deductive-nomological model of explanation in science. According to the Cause Law thesis, all true causal statements are such that some general causal law connects the cause and the effect under some description. Singular causal claims are made true, because there is an underlying general law of the form, All Xs cause Ys, such that the cause and the effect are instances of Xs and Ys. The singular claim, "that rock just broke this window," might be true, because "All rocks, thrown sufficiently hard, break windows," is true. This is where the nomological force of causal relationships comes from – the cause necessitates the effect because of the law connecting them, and without such a law, there would be no connection between cause and effect.

According to Davidson, causes and effects are those things out there in the world, to which we point with our descriptions. As such, Davidson holds that the same causes and effects can be picked out using different descriptions. When we make a true causal claim that x caused y, it is true because of that covering law, regardless of whether the covering law involves x and y so described or if it involves x and y under an entirely different description. Thus, the Cause Law thesis is an existence claim about there being a law under *some* description of the cause

and effect, not that there is a law for every description, nor that there is a law that we know, or even that we know the description under which the law holds. It is merely the claim that, whether or not we ever know it, there is such a description and such a law, and it is this which makes true any causal claim, including but not limited to those involving mental causes.

Putting these pieces together, Davidson holds that mental causes (and effects, although mental causation is primarily taken to be problematic for mental causes of physical events) are, extensionally, part of the same physical causal nexus that is studied by the sciences, and are thus causal, because they figure in true general laws. However, there are no laws containing mental terms – no laws in which both X and Y are mental, nor laws in which either X or Y are mental. Mental causes can be genuinely causal, but mental causes and effects are anomalous, because it is never as mental that they are covered by a law. Mental descriptions are one way of describing the causes and effects in questions, but not the only way. If one were to redescribe those same causes and effects in other terms, namely, in the right physical terms, then a general law of the form All Xs are Ys would cover every instance of true mental causation. But it would never cover it under the mental description.

In this way, Davidson hopes to salvage features of the mental, like rational constraints on action, while still situating mental causation within the same causal nexus as the causes and effects studies in the sciences. The kinds of causal relationships we find in physics cannot account for or accommodate what he called "the uneliminably normative or rational aspect of intentional idioms, and the consequent irreducibility of mental concepts to concepts amenable to inclusion in a closed system of laws" (Davidson 1995). Because the mental is anomalous, with no genuine laws involving mental terms, it cannot be reduced to the merely physical. Mental descriptions continue to be useful as a separate domain of discourse, even while acknowledging that the mental cause and effects in question are not anything above and beyond the physical causal nexus with which we are scientifically comfortable. The mental is simply another way, a nonreducible way, of describing certain parts of that nexus.

There are many issues that could be raised (and have been, by a wide variety of authors) with respect to Davidson's account. For instance, it relies on the rather antiquated deductive-nomological account of explanation, where causal explanations must all be made true by universal laws. Given other accounts of explanation and/or causation, it is not clear that anomalous monism could even be formulated, or that mental causation actually poses any kind of particular problem – we will explore this line of thought more in a subsequent section. Furthermore, it is something of a matter of faith that there really are multiple legitimate descriptions of the *same* mental causal relata. As we will also see in a subsequent section, there are many cases where redescribing causal relata actually changes the subject, by changing the causal relationships into which it enters. But for now, it suffices to lay out Davidson's view of anomalous monism as a key position that aimed to accommodate mental causation within the commitments of physicalism, against which the main challenge against genuine mental causation, that of causal exclusion, is targeted.

Davidson's account is the primary target for Jaegwon Kim's (1989, 2000) causal exclusion argument, which is arguably the core of the contemporary problem of mental causation. Kim challenges the idea that Davidson has salvaged genuine causal efficacy for the mental, and argues that it is instead a different form of reductive physicalism. Kim's challenge to anomalous monism can be generalized to pose an issue not just for mental causes, but for any causes that are in some way higher level with respect to another set of potential causal relata.

Kim's influential work involves both a specific criticism of Davidson's account as well as a broader challenge to any nonreductive account of the relationship between the mental and the physical. One of his main criticisms of Davidson's account of anomalous monism is that it does not actually establish genuine causal efficacy for the mental, and, thus, does not block the reduction of the mental to the physical. That some event has a mental description is causally irrelevant, claims Kim (1989). If it is only under a physical description that an event can be covered by a law, and it is only because of a covering law that an event is causally efficacious, then no mental event is ever causally efficacious because it is mental, but only because it is physical.

Horgan referred to this as the problem of quausation (1989): Mental events enter into causal relationships, but only as physical events, never by dint of their being mental events. The mental is an epiphenomenal ride-along of the physical, meaning that mental causation is merely apparent and nothing other than microphysical causation under a different name. Many authors find this an acceptable conclusion. But, in order to retain physicalism *and* genuine causal efficacy of the mental, something more is needed than simply having any kind of causal efficacy. It needs to be the right sort of causal efficacy, the sort attributable to mentality, not merely physicality.

The broader challenge that Kim has issued is often referred to as the causal exclusion problem. It applies to any nonreductive yet physicalist account of the mental, and sets out what must be overcome in order for mental causation to be genuinely mental, rather than an epiphenomenal redescription of genuine microphysical causation. Kim highlights the tension between physicalism and genuine mental causal efficacy by pointing out that the class of physical causes is supposed to be complete: For any physical effect, there is a sufficient cause of it that is physical, also. This is the rejection of dualism, of "spooky" nonphysical causation somehow bumping parts of the physical world around. According to anomalous monism, some physical causes are also mental causes. However, the effects of those causes are already "caused," as it were: For any physical effect, there is already a complete physical causal story.

One is then confronted with the following dilemma: Either such effects, with both physical and mental causes, are overdetermined or they are not overdetermined. If they are not overdetermined, then there is something that the mental contributes causally to the effect. But this also violates the assumption of physicalism. On the other horn of the dilemma, however, all effects with mental causes are overdetermined, which means that they have multiple causes, each of which is sufficient to bring about the effect. The physical causes alone, with no additional

mental cause, would have been sufficient to bring about the effect exactly as it occurred. This horn has two unfortunate consequences. It renders mental causes systematically superfluous, while also committing to a metaphysically suspect view about the incredibly rampant presence of overdetermination in the world for just a particular set of causes, namely, all and only the mental ones. Neither horn of this dilemma accomplishes the goal of preserving both physicalism and genuine causal efficacy of the mental.

The argument for causal exclusion is often accompanied by the following sort of diagram. M1 and M2 are singular tokens of particular mental events, and P1 and P2 are the corresponding physical event tokens on which the mental events depend.

$$\begin{tikzcd} M1 \arrow[r, dashed] \arrow[d, dash] & M2 \arrow[d, dash] \\ P1 \arrow[r, dashed] & P2 \end{tikzcd}$$

The vertical lines are of some kind of supervenience or ontological grounding relation between tokens of mental events and tokens of physical events. According to physicalism, all tokens of the mental must also be physical tokens. The horizontal line connecting P1 and P2 is causal: This represents the complete physical cause of P2. The question of mental causation is then the question of the causal efficacy of M1. There is an apparent causal relationship between M1 and M2. But, M1 supervenes on P1, and M2 supervenes on P2. P1 is a cause of P2, which means that there is already a complete cause for M2 in P1. Kim's claim is that M1 reduces to P1 as a cause: There is nothing about M2 that is leftover or uncaused, such that M1 can add by causally contributing to it. M1 does not cause P2, since the completeness of the physical means that P2 already has a sufficient physical cause, P1. What is left for M1 to do, asks Kim? M1 simply reduces to P1 in this picture, which means that the project of salvaging both physicalism and autonomous mental efficacy has failed.

The causal exclusion problem can be generalized to any set of token relata such that one kind of relata is identical with, supervenes on, is instantiated by, or is otherwise dependent on another kind of relata (see, for instance, Shapiro and Sober 2007). In other words, any so-called higher level phenomena will be subject to similar concerns about their genuine causal efficacy vis-à-vis their lower level counterparts. Evolutionary fitness, for instance, would, according to the generalized exclusion problem, have no causal efficacy of its own, being merely a stand-in for the causal efficacy of its lower level instantiations in individual instances of reproductive success. In the case of evolution, this may seem like the appropriate stance to take about the potential causal efficacy of higher level causes: We should refrain from reifying them all as having some additional mysterious kind of causal efficacy all their own. But in other cases, such as causal efficacy attributed to organisms as reproductive units, rather than, for instances, their genes, this is not as clearly the right result.

The generalized causal exclusion problem is the subject of criticism for the way in which it flattens causation, with the possibility of eliminating it altogether (see Block 2003). If the causal efficacy of higher level causes depends on or reduces to that of the lower level causes, then we can proceed to ask about the status of those lower level causes. Unless they are metaphysically bedrock, then they are in turn higher level than some other, yet-lower level causes. In this fashion, we proceed down to the microphysical, where we confront a new kind of dilemma. On one hand, we could commit to there being some lowest level such that only events at this level are genuinely causal. On the other hand, if there is no such lowest level, then causation "drains away" (Block 2003) into the bottomless abyss of the microphysical, and there is no genuine causal efficacy to be found anywhere.

The debate about causal drainage is somewhat off-topic for the issue of mental causation, but it helps keep a perspective on the urge to reduce higher level to lower level causes. While this may seem like a clearly justified maneuver in the context of a single pair of causal types (such as mental to physical, or psychological to neurophysiological), it requires making an assumption about what kinds of causes lack genuine efficacy, namely, those that are higher level with respect to other causes. This assumption may undercut the validity of the reduction by rendering those lower level causes just as inefficacious as the higher level ones. If neither the higher nor the lower have real causal efficacy, the impetus to reduce one to the other is greatly diminished.

There is some traction to be gained on the issue of causal exclusion and mental causation by considering the same structural problem for causal efficacy with different types of causes. Philosophers and scientists tend to have deeply entrenched views about what the "right" answer should be about mental causation, and this makes it easy to construct ad hoc "solutions" that have little merit other than yielding the correct conclusion, or to reject potentially viable accounts, because they get the wrong conclusion. By considering the same question applied to different relata, such as evolutionary fitness or thermodynamic temperature, we can assess different proposals reconciling or rejecting higher level causal efficacy on more neutral territory, and only then apply the solution to mental causation in particular.

The causal exclusion problem, applied to specifically mental causal relata, is the primary and dominant contemporary problem for mental causation. What is causing what, exactly, when we identify apparently mental causes, or offer causal explanations that rely on causal relationships involving mental relata?

Salvaging Mental Causation by Solving or Dissolving the Exclusion Problem

More solutions for solving the causal exclusion problem have been proposed in the last two decades than are possible to canvas in one place. The responses to this contemporary version of the problem of mental causation can be helpfully categorized in terms of the strategies they employ, however. Considering responses in

terms of these strategies is a useful way to map out the territory of ideas involved in the tangle of mental causation, mind-body relationship, reduction, explanation, and more.

Two popular general strategies are that of (i) changing the metaphysical type of the physical and mental tokens that are the relata in the above diagram, or (ii) changing the relationship posited between those tokens, such that the causal exclusion problem can no longer be formulated. Additional strategies involve various ways to bite the bullet, accepting that there is limited or no causal efficacy to the mental, and either (iii) rejecting the intuition that the mental should be treated as having causal efficacy, or (iv) offering a watered-down form of relevance for the mental that falls short of genuine causal efficacy but offers something more than pure epiphenomenalism. Two additional strategies dissolve the problem, rather than solving it directly: (v) denying the identity of mental and physical tokens, which means denying the relationship represented vertically in the above diagram, and (vi) challenging the implicit assumptions about causation on which the causal exclusion problem relies, with recourse to specific theories of causation. I will briefly discuss each of these strategies in order.

Strategy (i) starts by noting that the relata of mental and physical tokens used in formulating the causal exclusion problem could be of numerous different metaphysical types. A common approach is to follow Davidson and treat them as singular events, which is also convenient, since events are a very common relata type in theories of causation. Token mental events just are specific, very complicated, physical tokens, and the mental event tokens stand in all and only the causal relations in which the physical event tokens stand. Token-identity of events, however, leads straight to the causal exclusion problem whereby mental events do not have genuine causal efficacy. There are multiple potential candidates for the metaphysics of these tokens, but what unites these different accounts is that they each reconfigure the relata in the diagram above, as a way of attempting to block the reduction of the mental to the physical.

Instead of treating the mental and physical relata as events, one could construe them in terms of properties. Perhaps the mental is a second order property, i.e., a property had by some other, first order, property. If the mental is a second order property of first order physical properties, then it does not reduce away – it could be causally relevant or efficacious as a property of properties. There is thus only one token, having both physical, lower level, properties and mental, higher order, properties. Each instance of a mental property and a physical property are tokened by the same object. The mental property is multiply realizable, capable of being instantiated by a wide range of quite distinct physical tokens. As such, the mental properties do not reduce to the physical ones (see, on this, Bennett 2003; Levin 2010).

Strategy (ii) is similar to (i) in attempting to block causal exclusion by changing the characterization of the diagram above, but instead of focusing on the relata, the focus is on the relationships between them. The horizontal lines are causal; but what precisely is represented by the vertical lines? How one cashes out the relationship between the mental and the physical will affect the reducibility of mental causation

to physical causation. A common approach is that of some kind of supervenience of the mental on the physical (see especially Wilson 2005).

Supervenience can be a very broad asymmetric relationship, committing one to the claim that there can be no change in the mental without there also being a change in the physical, while there could potentially be a change in the physical without a change in the mental. For global supervenience, the mental parts of the world (be they events, properties, tropes, etc. – see strategy (i)) supervene on the entire physical world, such that any change, no matter how insignificant, might be sufficient for an entirely different set of mental relata to supervene. If we are considering the possible causal efficacy of Alice's intention to surprise Bob on the physical outcome of Bob's startled jump, then it is extremely counterintuitive to commit to the claim that the mental cause has changed because of a slight rearrangement of particles in a distant galaxy. Surely the mental relata supervene on a somewhat smaller batch of the physical world. Picking out what, exactly, goes into the patch of the physical world on which a particular candidate mental cause supervenes has proven to be a contentious issue.

Strategy (iii) involves denying the intuition that there is autonomous mental causation. Reductive physicalism of any stripe is an example of this, of which Kim himself is a well-known proponent. There are many versions of reductive physicalism, where the basic premise is that whatever the mental is, it reduces to or is nothing over and above the physical. Even stronger views, like eliminative physicalism (Churchland 1981), advocate the eventual eschewal of all mental terminology.

Strategy (iv) takes a somewhat different tack. Instead of simply denying the legitimacy of the intuition, some philosophers offer a replacement for genuine causal efficacy, something that explains why it seemed as if the mental were causally efficacious without having to grant full-blown mental causation. Jackson and Pettit (1990), for instance, distinguish between causal efficacy and causal relevance. Causal efficacy is what actually causes things to happen; causal relevance is what properties have such that they are cited in good causal explanations. But, while causally relevant properties may be explanatory, they lack causal efficacy. For example, according to this view, being fragile is causally relevant to the vase breaking, even though it was not the fragility that was causally efficacious in the actual breaking. This applies to the debate regarding mental causation by characterizing mental properties as causally relevant, even while it is always some other, quite specific, set of physical properties that are causally efficacious.

Strategy (v) is related to (i and ii) in that it focuses on the character of the relata and relationships in the diagram above, but instead of changing the kind of relationship between the mental and the physical, it argues that the vertical lines in the diagram do not exist. In other words, it denies the identity of token mental and physical relata, and by doing so, prevents the causal exclusion problem from being formulated. If the token of a mental event is not identical to or does not supervene solely on the token of a physical event, then the very way in which the problem is framed is specious (Andersen 2009).

There is a delicate balance to be struck in such strategies for responding to the causal exclusion problem for mental causation. The relationship between the mental and physical is itself as much a live issue for discussion, and as unresolved, as the existence or nature of mental causation itself. On the one hand, if we are willing to assume that the mental does have genuine causal efficacy, then we can use the causal exclusion problem as a rough guide toward how best to represent the relationship between the mental and physical. It would serve as a constraint on our representations that they yield the correct answer with respect to mental causation, and this would rule out some construals, such as token-identity of mental and physical events. It would not constrain enough to yield a single unequivocal solution, but it would be a substantive guide. On the other hand, though, we should be legitimately concerned about making this assumption about genuine mental causal efficacy, since we might take the causal exclusion problem to show exactly that this assumption is unwarranted. In that case, it is ad hoc to gerrymander our characterizations of the mental and the physical in order to reach the conclusion that the mental is genuinely efficacious. Rather than guiding us toward solving other problems like that of the mind-body relationship, it begs precisely the question at issue.

This leads to strategy (vi): Focus on causation as a way to situate mental causation in a broader perspective with better evidential footing. This tactic allows us to pose the question of whether or not, and in what way, the mental has genuine causal efficacy without having to make assumptions about how to best represent the relationship between the mental and physical relata in question. Accounts of causation provide independent evidential criteria for what it takes to count as a cause of something else; we can use these to investigate whether any mental "causes" actually meet the criteria for causation.

One way in which this has been done is to challenge the treatment of the mental and physical relata as sufficiently distinct that we can even sensibly ask the question about which one does the causing (Dardis 1993; Campbell 2010; Andersen 2009). Kim's original question, of whether it is M1 or P1 that causes M2, is misleading in that it asks us to implicitly treat these as distinct causal relata. They simply are not in competition, such that one – the physical – "wins out" over the other. Arguing from causal exclusion to the inefficacy of the mental is, on this strategy, a kind of category mistake.

Another way that strategy (vi) can be implemented to undermine the causal exclusion problem is to turn to contemporary accounts of causal explanation and see how mental causal relata fare on such accounts. Davidson's assumption about causation requiring general laws is widely rejected, and the causal exclusion problem cannot be formulated within many contemporary accounts of causation. In the last several decades, remarkable progress has been made in developing sophisticated philosophical and mathematical techniques for analyzing causal structure. We can translate the question of mental causation into specific accounts of causation to see if there is anything genuinely causal about the mental in each account. Once we do this, it turns out that on almost every contemporary account of causation, the mental has as much causal efficacy as any other cause outside of fundamental physics.

Consider an example of this. On the influential interventionist account of causation (Woodward 2003), the question of whether or not the mental has causal

efficacy is made more specific by considering a variety of causal variables that could represent different aspects of mental causation. One could ask about the role of conscious visual awareness in actions like reaching for and grasping objects. Each of these would be treated as a variable that takes on different values: perhaps Conscious visual experience (yes, no) and Reaching (hand preformed, hand not preformed). One would then consider the empirical research on this in order to determine if these two variables meet the criteria for having a causal relationship between them. Put very simply, this is a way of asking whether or not intervening on conscious visual awareness of an object changes the way in which we reach for those objects. Once we establish the answer (which, in this case, is yes – see Andersen 2009, Chap. 3), we have shown that there is at least one case of mental causation, namely, that which is represented by the variables in question.

Against this kind of mathematically sophisticated and scientifically grounded account, Kim's causal exclusion argument looks rather simplistic and naïve. One might want to protest that the variables are just a stand-in for the real causal story, which surely involves just the neurophysiological processes initiated by light impinging on the retina, and so forth. To defend this response in the face of a well-validated account of causation that has independent justification for its requirements on what counts as a cause, one should have more than just the intuition that the "real" causal story is elsewhere. This is a key advantage to treating the problem of mental causation as one of causation in general, rather than one of mental causes as sui generis: Given such well-established and explicitly justified methods for finding causal structure, it takes a great deal to show that the answer yielded by accounts of causation such as interventionism is incorrect. This puts the onus on reductive physicalists to show what is wrong in such analyses and to offer a more substantive defense of what counts as a "real" causal story, a very challenging task.

These six different argumentative strategies cover a vast number of different accounts, organized in terms of commonalities they share with regard to the aspect of the causal exclusion problem that they address. While there are multiple aspects to the issue of mental causation, there is no doubt that this problem, reconciling genuine mental efficacy with a physicalist view of the world and an ambiguous relationship between the mental and physical, is one of the main debates in contemporary philosophy of mind.

Conclusion and Future Directions

The causal exclusion problem is interesting for the way in which it captures so clearly the dilemma for genuine mental causation. The generalized exclusion problem raises issues for many different kinds of higher level causes, including the mental as well as a huge host of other potential causal relata from various sciences. However, the version of causal exclusion that applies to the issue of mental causation has, as we have seen, a unique twist that renders it particularly difficult to deal with. There is no clear answer to the question of how the levels in question are related to one another.

It is often tempting to treat mental causes as simply stand-ins for the "real" causal story, which must be purely physical and involve neurophysiological processes. After the last section, we should be cautious about this practice. Once we meet the evidential requirements for independently justified accounts of causation for the mental to have genuine causal efficacy, it is unnecessary to reject mental causation by claiming that "really" what we have just shown is somehow false or merely apparent. Furthermore, it is a substantive task to translate one potential relatum into another. Moving too quickly from the mental to the neurophysiological risks changing the subject, where the new physical process or event may be causally efficacious, but not efficacious *of the same effect* as was the original mental relatum.

This is where much of the future work regarding mental causation may be directed: toward a careful and detailed elaboration of the variety of ways in which mental causal relata can be translated into a format such that accounts of causation, coupled with results from cognitive neuroscience and psychology, can yield specific answers. The causal exclusion problem pitches mental causation as an all or nothing problem: Either it is causal or it is not. Moving away from this approach means moving toward a scientifically enriched process using well-confirmed tools from studies of causation. The goal then becomes to suss out the structure of mental causation and how it is situated in larger structures of the body and the environment.

Davidson was onto something when he said that mental causation, whatever it was, needed to be the same ordinary sort of causation that is studied in the sciences. It cannot be something different or new without thereby bringing in the sorts of mysterious powers that anyone with a commitment to physicalism of any stripe should want to avoid. He was wrong about what that kind of causation is – there is no need to assume unknowable universal laws governing physical redescriptions of mental causal relata. The way forward in this debate will be through foregrounding the issue of causation, making the question of mental causation more explicitly one of mental *causation*.

Abstract

Nervous systems perform amazing control functions, which include driving complex locomotive systems in real time. How do they do it? The best explanation neuroscientists have found is that nervous systems collect information from the organism and the environment, use that information to construct representations, and perform computations on such representations. of neural computations drives the organism. This article discusses what it means for nervous systems to carry information, to represent, and to perform computations.

Neural Information

This section discusses information, a ubiquitous notion which turns out to have multiple senses. Particularly when dealing with neural systems, it is important to distinguish what kind of information is being discussed. The most relevant notions are Shannon information – a precise, mathematical notion often used in characterizing neural systems – and natural semantic information, an informal but useful notion of information that lets us begin to assign meanings to neural events.

Neural Information I: Shannon Information

In his mathematical theory of information, Shannon (1948) defined two quantitative measures of information, *entropy* and *mutual information*. Shannon entropy is a quantitative, objective measurement of how informative a state change is in a system. Very generally, if a system goes from one state to another, the informational "value" of the second state is greater if the chances of moving to that state are very low; if it is very likely that the system move to that second state, it is less informative.

More formally, entropy can be defined as follows. Let X be a discrete random variable such that X takes values in $\{x_1, x_2, \ldots x_n\}$ with respective probabilities $p(x_1), p(x_2), \ldots p(x_n)$. We assume that these probabilities are all greater than zero, and that the sum of the probabilities is equal to one. The entropy of the random variable is defined as follows:

$$H(X) = -\sum_{j=1}^{n} p(x_j) \log_2 p(x_j).$$

The entropy tells us how much information is transmitted by a random variable. So, for example, if X represents flips of a fair coin, then it takes values of heads or tails with probability 0.5. The entropy in that case is 1, which means that exactly one "bit" of information is gained by each transmission/reception of X. If heads becomes more probable than tails (as in the case of a loaded coin), however, then the entropy decreases, which coincides with the intuitive idea that less information is gained if we know that heads is more likely. If we take the extreme case in which heads is certain, then the entropy is zero: if we already know that the coin must be heads, learning that it is heads on a particular flip makes no difference. Another way to view entropy is as a measure of uncertainty about the state of a system: a decrease in a system's entropy means we are more certain about what state (or states) the system will be in. In our coin example, as entropy approaches zero, the uncertainty of its landing heads decreases.

The second quantitative measure Shannon introduced is called mutual information. Informally, mutual information is a measure of how much we can determine about one variable given another variable. If two variables are independent, then nothing can be known about one by observing the other, and their mutual information is zero. But non-zero mutual information about two variables implies that the state of one variable makes it more likely that the second variable is in certain states than others.

Formally, mutual information is given by:

$$I(X, Y) = \sum_{x \in X} \sum_{y \in Y} p(x, y) \log\left(\frac{p(x, y)}{p(x)p(y)}\right)$$

As before, X is a discrete random variable, and so is Y. The term $p(x, y)$ is the joint probability of X and Y. Note that mutual information is *mutual*: non-zero mutual information between X and Y is precisely the same between Y and X.

One of the most immediate and important uses of information theory is known as coding theory. Here, information theory is used to analyze and design communication systems. In real-world systems, noise of some sort is introduced into the signal going from the sender to the receiver, and the central task of coding theory is to design ways of encoding information such that the intended message is retrievable in the presence of such noise. More important for the present discussion is the application of information theory to neural signaling, in which neural systems are analyzed using the tools of coding theory.

Using information theory in this way, neuroscientists can study neural signaling systems. It is uncontroversial that neural firings – action potentials, or excitatory postsynaptic potentials (EPSPs) – are the primary means by which neural communication occurs, and which thus undergirds the sensory, cognitive, and motor processes for which the brain is responsible. One example comes from Borst and Theunissen (1999): here, the authors use coding theory to analyze the information content carried by spikes from individual neurons according to different models of neural spiking. Furthermore, they demonstrate that information theory can be used to show that so-called temporal codes, in which the relative time between individual spikes is thought to carry information, do not seem to be a good model for how information is transmitted in most neural systems.

In summary, Shannon entropy and mutual information play an important role in analyzing neural systems – much can be learned about the ways that neurons generate action potentials and respond to these signals by applying Shannon's quantitative measures of information – but only in a limited way. For neither entropy nor mutual information tell us what any particular signal means – what any particular signal tells us about any particular state of affairs. Whenever there is mutual information between a source and a receiver, by definition the receiver obtains information *about* the sources – that is, the receiver learns something about what happens at the source. This can be the basis for a useful notion of semantic information.

Neural Information II: Natural Semantic Information

When we want to know what a particular alarm means, or what a word in a foreign language means, we are certainly asking about the information conveyed in each case, but not in the sense of Shannon information. We call this kind of information "semantic information," adopt Grice's influential distinction between "natural" and "non-natural" semantic meaning (Grice 1957), and apply it to natural information.

Natural semantic information is the information conveyed about a state of affairs by way of some natural process. A paradigmatic example is the information gained when one sees a column of smoke rising in the forest: the smoke carries the information that there is a fire, and so seeing smoke allows us to infer that there is a fire near the base of the smoke column. Smoke carries natural information about fire because it reliably correlates with fire. Thus, we will say that a signal carries natural semantic information about what it reliably correlates with.

There are many examples of natural semantic information in neural systems. A few examples include place cells, grid cells, and feature detectors. Place cells are hippocampal neurons that fire preferentially when an organism is in a particular location in its local environment: a particular place cell fires most vigorously when the animal is in a particular place. One place cell might fire when the organism is in a particular corner of its enclosure; another might fire when it's in a different corner. Grid cells function similarly, but instead of firing preferentially when the animal is in a particular *place*, grid cells fire at regular intervals within the local environment. If we were to map the grid cells that fire as an animal moves within its environment, a regular, triangular "grid" would become apparent, suggesting that the grid cell system tracks the animal's location relative to an imaginary grid laid out over its environment. The place cells, however, might only be sensitive to a small number of locations, such as particular "landmarks" within the environment, but not others (Moser et al. 2008).

The class of neurons known as feature detectors is another good example of a system that carries natural semantic information. Beginning with the seminal work of Hubel and Wiesel, neuroscientists have demonstrated that certain neurons in the visual system fire preferentially when the organism is viewing particular visual patterns, such as lines, angles, shapes, or images moving in a particular direction (Hubel and Wiesel 1962). So, for example, one neuron might fire most vigorously when the animal is viewing a horizontal line, while another fires most vigorously when the animal is viewing a vertical line. By combining this information, neurons "upstream" from these basic feature detectors form more complex feature detectors, able to detect, for example, the edges of objects and environmental scenes (Marr and Hildreth 1980).

These are all examples in which neuroscientists have experimentally demonstrated reliable correlations between environmental features and the firing (or firing patterns) of neurons. These carriers of natural semantic information are obviously quite important to organisms: grid and place cells are part of the explanation for how animals navigate, and feature detectors are part of the explanation for how animals recognize aspects of their environment. Note again that this sense of

information is stronger than that of Shannon information: while neural systems involved in the processing of natural semantic information can be analyzed in terms of Shannon information, a system that can be analyzed in Shannon information-theoretic terms need not carry natural semantic information at all. We can measure the entropy of a neural spiking event without knowing (or caring) about what the spikes are *about*. For example, Strong et al. (1998) demonstrate how to calculate the entropy of signals from a neuron known as H1, based on the time between spikes. They mention that although neuroscientists understand what H1 represents, that has nothing to do with the analysis they are proposing, which is of H1's informational entropy.

This section outlined two different senses of information. Beyond mere conceptual clarity, it is useful to make clear which one of these two senses is being deployed in neuroscientific and philosophical discussions of the mind/brain. The claim that a particular neural system is processing information, or is being understood as an information processing system, may mean nothing more than that the system is being analyzed in terms of its Shannon-information properties; that is no guarantee that a system is capable of carrying semantic information. Furthermore, characterizing a system as capable of processing information is no guarantee that the system manipulates – or should be understood as manipulating – representations.

Neural Representation

Having distinguished different senses of information gives us the tools we need to make clear when precisely an instance of neural information-carrying is an instance of neural representation. The standard account of what a representation is will not do for neuroscience, but there are kinds of neural information-carrying that are instances of neural representation in a sense that serves neuroscience well.

The Standard Conception of Representation

The received view of representation may be found in C. S. Peirce's seminal work on what he called signifiers (Peirce 1992). Using contemporary terminology, representations consist of three essential aspects. First, there is the thing to be represented, often called simply the *object*. Next, there is the thing that represents that object: the *representation* (Peirce calls this the *signifier*). Finally, there is the *subject* or *agent* who interprets the representation as being about, in some way or another, the object (Peirce calls this the *interpretant*). A simple example might be a drawing of a cat. The object is the cat itself, the representation is the drawing, and the agent is whoever sees the drawing as being about the cat.

There are several difficulties with the standard conception of representation. One difficulty is how to understand the "being about" relation mentioned above. Peirce noted that there are three ways in which representations are about their objects.

Representations can be correlated with their objects (compare with the above discussion of natural semantic information): smoke can represent fire because smoke is caused by fire. Representations can also resemble their objects: a picture of a fire is about a fire because it resembles a fire, at least in its visual aspects. Last, representations can be about objects by convention: the word "fire" is about fire because this is the word that English language speakers agree to use for this purpose.

There remains a problem with the role of the agent (interpretant). Peirce's three-place account works quite well for everyday examples of representation. But it won't work for an account of representation appropriate to neuroscience. To see why, consider a simple example, such as the claim that certain patterns of activation in a particular neural system represent faces. The object and representation are clear: they are a particular face, and a particular pattern of activation, respectively. But what is the interpretant? It can't be the whole organism, because organisms do not have that kind of access to the activity of their neural systems. Positing that some subsystem of the organism is the interpretant amounts to equating that subsystem with a homunculus: another agent with the representational capacities to recognize that the representation is about the object. The problem with homuncular explanations is clear: what we are trying to explain by positing representations is some capacity of the organism, and positing homunculi with the very capacities we are trying to explain is no explanation at all. It can't be homunculi all the way down!

Thus, what's needed is a conception of representation that both avoids the problem of homuncular regress and warrants being taken seriously as a conception of *representation*, rather than something else.

A Functional Conception of Representation

The problem with standard accounts is that an interpretant is necessary to make sense of what a representation is about. An alternative account eliminates the role of the interpretant and posits that a representational system's *function* can undergird the fact that representations within that system are about particular objects (e.g., Dretske 1988). This allows us to understand representations without positing homunculi.

So how does a functional account accomplish this? Consider the example of a gas gauge that shows the amount of gas in a car by the weight of the tank. The gauge indicates a number of things: the weight of the gas, the force due to gravity being exerted on the bolts holding the gas tank to the car, and so on. While the gauge carries natural semantic information about all of these things, it only *represents* one thing: the amount of gas in the tank. This is because the function of the gauge is to carry natural semantic information about the amount of gas, but not the gravitational force on certain bolts. This function is important for the control of certain behaviors, such as illuminating a low-fuel light, and alerting the driver when it is time to get more gas.

This idea extends usefully to natural systems: the pattern of activation within a neural system, for example, might *indicate* many things, such as the amount of neurotransmitter or mean electrical activity in a given region, but it only *represents*, say, the angle of the organism's limb. This pattern of activity represents limb angle because carrying natural semantic information about limb angle is the *function* of the neural system, and not because there is anyone – a homunculus or an outside observer – interpreting those neural firings as being about limb angle.

This account relies heavily on the notion of function. Scientists – particularly those working in the special sciences – appeal to this notion of function with some frequency, and a number of philosophers have gone some way toward providing accounts of biological functions that are both philosophically satisfactory and do justice to the practices of working scientists (some examples include (Allen and Bekoff 1995; Bigelow and Pargetter 1987; Godfrey-Smith 1994; Millikan 1989)).

Some Neural States are Representations

Everything that was said above can be put together to make clear when a neural state, or a part of a neural system, is genuinely a representation, or processing representations. To reiterate, it is not enough that a neural system carries information; the kind of information being carried matters. Trafficking in Shannon-information is not enough; the system must carry natural semantic information. But carrying natural semantic information is still not enough to generate a representation: tree rings may carry natural semantic information about the number of times the earth has revolved around the sun since the birth of the tree, but those rings do not represent anything at all: they do not have the function of representing. What is required is that natural semantic information is carried or processed in a way such that the system containing that information has the function of carrying that information.

A specific example from neuroscience may be useful at this point. Romo and colleagues describe several cases involving monkeys in which researchers have demonstrated the correlation between particular neural systems and the stimulation of the monkeys' skin (Romo et al. 2002). The particular stimulation involved is vibrotactile: the stimulus vibrates on the surface of the monkeys' fingers at variable frequencies and intensities, which the experimenters control. A number of experiments have demonstrated that there are direct correlations between the patterns of activity in particular neurons in the primary somatosensory cortex (called S1) and the particular kind of stimulation applied to monkeys' fingers; thus, these neurons carry natural semantic information about an external stimulus. More interestingly, the monkeys can be trained to perform tasks that require discriminating particular patterns of stimulation from other such patterns; this strongly suggests that the function of these neurons in S1 is to detect this kind of stimulation. If so, these neurons represent the pattern of stimulation on the monkeys' fingers, and the information carried by this representation is used in other parts of the monkeys' cortex in discrimination tasks that are sensitive to this information.

The above sections have shown that information processing and representation are two separate things: although representation involves carrying information, information-carrying may not involve any representation at all. The final section addresses how these notions relate to computation in neural systems.

Neural Computation

Computation is often considered the same thing as information processing or representation manipulation (e.g., Fodor 1981). But while computation is often used to process information and manipulate representations, computation can also occur without information or representation (Piccinini 2008). Therefore, we offer an account of computation that is applicable to neuroscience but does presuppose representation or information processing. Such an account paves the way for assessing different versions of a doctrine known as computationalism, according to which the nervous system is a kind of computing system.

Computation: A Mechanistic Account

According to the mechanistic account of computation (Piccinini and Scarantino 2011), a computation in the most general sense is the processing of vehicles (state variables) according to rules that are sensitive to certain vehicle properties, and specifically, to differences between different portions of the vehicles. This processing is performed by a functional mechanism, which is a mechanism whose components are functionally organized to perform the computation (i.e., the organized components have the function of performing a computation). Thus, if the mechanism malfunctions, a miscomputation occurs.

When we define concrete computations and the vehicles that they manipulate, we need not consider all of their specific physical properties. Rather, we only need to consider the properties that are relevant to the computation as specified by the rules defining the computation. A physical system can be described at different levels of abstraction; since concrete computations and their vehicles are described at a level of abstraction defined independently of the physical media that implement them, we call them *medium-independent*.

To put the point another way, a vehicle is medium-independent when the rules (i.e., the input–output maps) that define a computation are sensitive only to differences between portions of the vehicles along specific dimensions of variation, and insensitive to any other concrete physical properties of the vehicles. Thus, a given computation can be implemented in different physical media (e.g., mechanical, electro-mechanical, electronic, magnetic, etc.), provided that the media possess a sufficient number of dimensions of variation (or degrees of freedom) that can be appropriately manipulated, and that the components of the implementing mechanism are functionally organized in the appropriate way.

Computationalism

Computationalism is the view that cognitive capacities have a computational explanation or, somewhat more strongly, that cognition just is a kind of computation. In what follows, these two formulations are used interchangeably. Many neuroscientists endorse some version of computationalism: when neuroscientists propose an explanation of a cognitive capacity, the explanation typically involves computations underlying the cognitive capacity. But neuroscientists and cognitive scientists differ on how they apply the notion of computation to the study of cognition. Their three main research traditions are classical computationalism, connectionism, and computational neuroscience.

The best computational theories appeal to a well-defined kind of computation. Historically, the most influential version of computationalism appeals to digital computation – the kind of computation performed by digital computers. Other versions appeal to analog computation or computation in a generic sense, which encompasses both digital and analog computation as species.

Three Research Traditions: Classical Computationalism, Connectionism, and Computational Neuroscience

The view that thinking has something to do with computation may be found in the works of some early modern materialists, such as Thomas Hobbes (Boden 2006). But computationalism properly began in earnest after a number of logicians (most notably Alonzo Church, Kurt Gödel, Stephen Kleene, Emil Post, and especially Alan Turing) laid the foundations for the mathematical theory of computation.

Turing (1936–7) analyzed computation in terms of what are now called Turing Machines (TMs) – a kind of simple, idealized processing unit operating on an unbounded tape. The tape is divided into squares, upon which the processor can write symbols or read existing symbols. The processor moves along the tape reading and writing on one square at a time. The processing unit's behavior – what symbol to write, where to move – is governed by rules; these rules specify what to do depending on what is on the tape as well as which of finitely many states the processor is in.

Turing argued convincingly that any function on the natural numbers that can be computed by following an algorithm (i.e., an unambiguous list of instructions operating on discrete symbols) can be computed by a TM. Church offered a similar proposal in terms of general recursive functions, and it turns out that a function is general recursive if and only if it can be computed by a TM. Given this extensional equivalence between TMs and general recursive functions, the thesis that any algorithmically computable function is computable by some TM (or equivalently, is general recursive) is now known as the Church-Turing thesis.

Turing made two other relevant contributions. First, he showed how to construct what are now called Universal Turing Machines (UTMs). These are TMs that can mimic any other TM by encoding the rules that govern that machine as instructions,

storing the instructions on a portion of their tape, and then using the encoded instructions to determine their behavior on the input data. To put this in more modern terms, UTMs can take in a description of any TM and use that description as a program. Notice that ordinary digital computers, although they have more complex components than UTMs, are universal in the same sense (up to their memory limitations). That is, digital computers can compute any function computable by a TM until they run out of memory.

Second, Turing showed that the vast majority of functions whose domain is denumerable (e.g., functions of strings of symbols or of natural numbers) are actually *not* computable by TMs. These ideas can be put together as follows: assuming the Church-Turing thesis, a universal digital computer can compute any function computable by algorithm, although the set of these Turing-computable functions is a tiny subset of all the functions whose domain is denumerable.

Modern computationalism began when Warren McCulloch and Walter Pitts connected three things: Turing's work on computation, the explanation of cognitive capacities, and the mathematical study of artificial neural networks. Artificial neural networks are sets of connected signal-processing elements ("neurons" or "nodes"). Typically, they have nodes that receive inputs from the environment (input elements), nodes that yield outputs to the environment (output nodes), and nodes that communicate only with other nodes in the system (hidden nodes). Each node receives input signals and delivers output signals; the output is a function of the received input and the node's current state. As a result of their nodes' activities and organization, neural networks turn the input received by their input nodes into the output produced by their output nodes. A neural network may be either a concrete physical system or an abstract mathematical system. An abstract neural network may be used to model another system (such as a network of actual neurons) to some degree of approximation.

The mathematical study of real neural networks using biophysical techniques began around the 1930s. McCulloch and Pitts were the first to suggest that neural networks have something to do with computation. They defined networks that operate on sequences of discrete inputs in discrete time. They then argued that their networks are a useful idealization of real neural networks, and concluded that the activity of their networks could explain cognitive phenomena. McCulloch and Pitts also pointed out that their networks can perform computations like those of TMs. More precisely, McCulloch-Pitts networks are computationally equivalent to TMs without tape (or finite state automata). Modern digital computers are a kind of McCulloch-Pitts neural network. Digital computers are sets of logic gates – digital signal-processing elements equivalent to McCulloch-Pitts neurons – connected to form a specific architecture.

McCulloch and Pitts's account of cognition contains three important aspects: an analogy between neural processes and digital computations, the use of mathematically defined neural networks as models, and an appeal to neurophysiological evidence to support their neural network models. After McCulloch and Pitts, many others linked computation and cognition, though they often abandoned one or more aspects of McCulloch and Pitts's theory. Computationalism evolved into three main traditions, each emphasizing a different aspect of McCulloch and Pitts's account.

One tradition, sometimes called classical computationalism, emphasizes the analogy between cognitive systems and digital computers while downplaying the relevance of neuroscience to the theory of cognition. When researchers in this tradition offer computational models of a cognitive capacity, the models take the form of computer programs for producing the capacity in question. One strength of the classicist tradition lies in programming computers to exhibit higher cognitive capacities such as problem solving, language processing, and language-based inference.

A second tradition, most closely associated with the term "connectionism" (although this label can be misleading; see below), downplays the analogy between cognitive systems and digital computers in favor of computational explanations of cognition that are "neurally inspired". When researchers in this tradition offer computational models of a cognitive capacity, the models take the form of artificial neural networks for producing the capacity in question. Such models are primarily constrained by psychological data, as opposed to neurophysiological and neuroanatomical data. One strength of the connectionist tradition lies in designing artificial neural networks that exhibit cognitive capacities such as perception, motor control, learning, and implicit memory.

A third tradition is most closely associated with the term computational neuroscience, which is one aspect of theoretical neuroscience. Computational neuroscience downplays the analogy between cognitive systems and digital computers even more than the connectionist tradition. The reasons for this are less straightforward than it seems, but it does appear that the functional relevance of neural signals depends on non-discrete aspects of the signals such as firing rates and spike timing. More specifically, current neuroscientific evidence suggests that typical neural signals, such as spike trains and spike timings, are graded like continuous signals but are constituted by discrete functional elements (spikes); thus typical neural signals are neither continuous signals nor strings of digits. Therefore, a strong case can be made that typical neural signals are neither continuous signals nor strings of digits, and that in the general case neural computation is neither digital nor analog but sui generis (Piccinini and Bahar 2013).

Neurocomputational models aim to describe actual neural systems such as (parts of) the hippocampus, cerebellum, or cortex, and are constrained by neurophysiological and neuroanatomical data in addition to psychological data. It turns out that McCulloch-Pitts networks and many of their "connectionist" descendents are relatively unfaithful to the details of neural activity, whereas other types of neural networks are more biologically realistic. Computational neuroscience offers models of how real neural systems may exhibit cognitive capacities, especially perception, motor control, learning, and implicit memory.

Although the three traditions just outlined are in competition with one another to some extent, there is also some fuzziness at their borders. Some cognitive scientists propose hybrid theories, which combine explanatory resources drawn from both the classicist and the connectionist traditions. In addition, biological realism comes in degrees, so there is no sharp divide between connectionist and neurocomputational models.

Understanding the Three Traditions

The debate between classicists and connectionists has been somewhat confusing. Different authors employ different notions of computation, which vary in both their degree of precision and their inclusiveness. Specifically, some authors use the term 'computation' only for classical computation – i.e., algorithmic digital computation over language-like structures – and conclude that connectionism falls outside computationalism. By contrast, other authors use a broader notion of computation, thus including connectionism within computationalism. But even after we factor out differences in notions of computation, further confusions can be easily found.

Classical computationalism and connectionism are often described as being at odds with one another for two reasons. First, classical computationalism is committed to the idea that the vehicles of digital computation are language-like structures. Second, classical computationalism is taken to be autonomous from neuroscience. Both of these theses are flatly denied by many prominent connectionists. But some connectionists also model and explain cognition using neural networks that perform computations defined over digital structures, so perhaps they should be counted among the digital computationalists.

Furthermore, both classicists and connectionists tend to ignore computational neuroscientists, who in turn tend to ignore both classical computationalism and connectionism. Computational neuroscientists often operate with their own mathematical tools without committing themselves to a particular notion of computation. To make matters worse, some connectionists and computational neuroscientists reject digital computationalism – they maintain that their neural networks do not perform digital computations.

In addition, the very origin of digital computationalism calls into question the commitment to autonomy from neuroscience. McCulloch and Pitts initially introduced digital computationalism as a theory of the brain, and some form of computationalism or other is now a working assumption of many neuroscientists. For example, Koch (1999) begins with these two sentences: "The brain computes! This is accepted as a truism by the majority of neuroscientists engaged in discovering the principles employed in the design and operation of nervous systems."

A further wrinkle derives from the ambiguity of the term "connectionism." In its original sense, connectionism says that behavior is explained by the changing "connections" between stimuli and responses, which are biologically mediated by changing the strength of the electrochemical connections between neurons. This original connectionism is a descendant of associationist behaviorism, so it may be called associationist connectionism. According to associationist behaviorism, behavior is explained by the association between stimuli and responses, that is, organisms learn through reinforcement to respond to stimuli in certain ways. Associationist connectionism adds to associationist behaviorism a biological mechanism to explain these associations: modifying the strength of the connections between neurons.

But contemporary connectionism is a more general thesis than associationist connectionism. In its most general form, contemporary connectionism, like

computational neuroscience, simply says that cognition is explained (at some level) by the activity of neural networks. This is a truism, or at least it should be. The brain is the organ of cognition, the cells that perform cognitive functions are (mostly) neurons, and neurons perform their cognitive labor via their activity in networks. Neural activity is computation at least in a generic sense. Because digital computers are a special kind of neural network, even classicists, whose theory is most closely inspired by digital computers, are committed to connectionism in its general sense.

The relationship between connectionist and neurocomputational approaches on one hand and associationism on the other turns on a distinction between strong and weak associationism. Strong associationism maintains that association is the only legitimate explanatory construct in a theory of cognition. Weak associationism maintains that association is a legitimate explanatory construct along with others such as the innate structure of neural systems.

To be sure, some connectionists profess strong associationism. But that is beside the point, because connectionism *per se* is consistent with weak associationism or even the complete rejection of associationism. Some connectionist models do not rely on association at all – a prominent example being the work of McCulloch and Pitts. Weak associationism is consistent with many theories of cognition, including classicism. A vivid illustration is Alan Turing's early proposal to train associative neural networks to acquire the architectural structure of a universal computing machine. In Turing's proposal, association may explain how a network acquires the capacity for universal computation (or an approximation thereof), while the capacity for universal computation, in turn, may explain any number of other cognitive phenomena.

Although many of today's connectionists and computational neuroscientists emphasize the explanatory role of association, many of them also combine association with other explanatory constructs, as per weak associationism. What remains to be determined is which neural networks, organized in what way, actually explain cognition and which role association and other explanatory constructs should play in a theory of cognition.

Yet another source of confusion is that classical computationalism, connectionism, and computational neuroscience tend to offer explanations at different mechanistic levels. Specifically, classicists tend to offer explanations in terms of rules and representations, without detailing the neural mechanisms by which the representations are implemented and processed; connectionists tend to offer explanations in terms of highly abstract neural networks, which do not necessarily represent networks of actual neurons (in fact, a processing element in a connectionist network may represent an entire brain area rather than an actual neuron); finally, computational neuroscientists tend to offer explanations in terms of mathematical models that represent concrete neural networks based on neurophysiological evidence. Explanations at different mechanistic levels are not necessarily in conflict with each other, but they do need to be integrated to describe a multi-level mechanism. Integrating explanations at different levels into a unified multi-level mechanistic picture may require revisions in the original explanations themselves.

Different parties in the dispute between classical computationalism, connectionism, and computational neuroscience may offer different accounts of how the different levels relate to one another. One traditional view is that computational explanations do not describe mechanisms. Instead, computational and mechanistic explanations are independent. This suggests a division of labor: computations are the domain of psychologists, while the implementing neural mechanisms are the business of neuroscientists. According to this picture, the role of connectionists and computational neuroscientists is to discover how neural mechanisms implement the computations postulated by (classicist) psychologists.

This traditional view has been criticized as unfaithful to scientific practices. It has been pointed out that, first, that neuroscientists also offer computational explanations (not just psychologists); second, far from being independent, different levels of explanation constrain one another; and finally, both computational explanations and mechanistic explanations can be given at different levels.

One alternative to the traditional view is that connectionist or neurocomputational explanations simply replace classicist ones. Perhaps some connectionist computations approximate classical ones. In any case, some authors maintain that classicist constructs, such as program execution, play no causal role in cognition and will be eliminated from cognitive science.

A more neutral account of the relation between explanations at different levels is provided by the mechanistic account of computation. According to the mechanistic account, computational explanation is just one type of mechanistic explanation. Mechanistic explanations provide components with such properties and organization that they produce the phenomenon. Computational explanation, then, is explanation in terms of computing mechanisms and components – mechanisms and components that perform computations. Mechanistic explanations come with many levels of mechanisms, where each level is constituted by its components and the way they are organized. If a mechanistic level produces its behavior by the action of computing components, it counts as a computational level. Thus, a mechanism may contain zero, one, or many computational levels, depending on what components it has and what they do. Which types of computation are performed at each level is an open empirical question to be answered by studying cognition and the nervous system at all levels of organization.

Conclusion

Computationalism is here to stay. There is every reason to suppose that cognitive capacities have computational explanations, at least in a generic sense. Moreover, everyone agrees with (or should agree with) connectionists or computational neuroscientists, at least in the general sense of embracing neural computation over neural representations. Nonetheless, much work remains to be done.

A complete computational study of cognition will require that we integrate different mechanistic levels into a unified, multi-level explanation of cognition. We also need to characterize the specific computations on which cognition

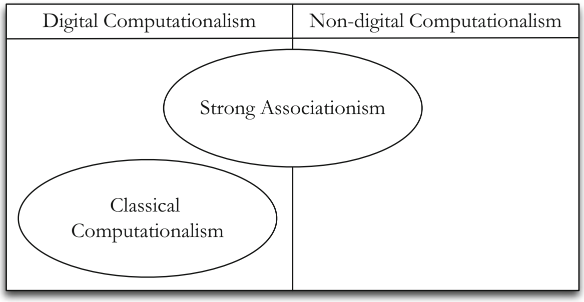

Fig. 6.1 Some prominent forms of computationalism and their relations

depends: whether – and to what extent – the satisfactory explanation of cognition requires classical computational mechanisms as opposed to non-classical digital computation, and whether we need to invoke processes that involve non-digital computation (Fig. 6.1). It may turn out that one computational theory is right about all of cognition, or it may be that different cognitive capacities are explained by different kinds of computation. To address these questions in the long run, the only effective way is to study nervous systems at all its levels of organization and find out how they exhibit cognitive capacities.

Abstract

Research on moral cognition is a growing and heavily multidisciplinary field. This section contains chapters addressing foundational psychological, neuroscientific, and philosophical issues of research on moral decision-making. Furthermore, beyond summarizing the state of the art of their respective fields, the authors formulate their own proposals to answer open questions such as those on the relation between emotion and cognition in moral psychology, the idea that there is a "moral module" in the human brain, the relevance of this research for ethics and meta-ethics, the various psychological and philosophical meanings of "intuition" and how intuitions can have a justificatory role, or the connection between the psychological, neuroscientific, and philosophical levels in popular experiments on moral cognition. Research on moral decision-making is challenging, for empiricists as well as theoreticians, and is related to several applied questions of neuroethics which are briefly addressed at the end of this introduction.

Introduction: Moral Cognition

The early twenty-first century has seen an increasing academic interest in moral cognition that has been truly multidisciplinary, connecting branches of philosophy with empirical disciplines, reconsidering traditional questions of ethics or meta-ethics – for those unfamiliar with the term: "the attempt to understand the metaphysical, epistemological, semantic, and psychological, presuppositions and commitments of moral thought, talk, and practice" (Sayre-McCord 2012) – as well as age-old debates in the light of new scientific evidence (see Fig. 7.1). To name just two broad and important examples which are stimulated by new psychology and neuroscience findings and which are also intensively discussed in the contributions to this section: First, the question of the nature and role of moral reasoning, emotion, or intuition and, second, the question of whether there are natural moral facts and properties, perhaps even "hard-wired" into our brain, as once suggested by Michael Gazzaniga (2005).

Philosophers have debated whether moral judgments *should* be based in the passions or in reason, with the Scottish philosopher David Hume being a famous proponent of the passions (Hume 1777/1975) and the German philosopher Immanuel Kant an eminent advocate of reason (Kant 1785/2011; for a compilation of historical readings, see Nadelhoffer et al. 2010). Sometimes inspired by that traditional historical debate but with a different question in mind, psychologists tried to understand *how* moral judgments *are actually made* by lay people or certain kinds of experts, sometimes with an emphasis on the development of their moral faculties as they mature from childhood to adulthood or as a function of their education (Gilligan 1982; Kohlberg 1984; Lind et al. 2010; Piaget 1932), sometimes focusing on situational characteristics of a particular environment influencing moral judgments (Haidt 2001; Pizarro 2000).

With the expansion of cognitive neuroscience and the neuroscience turn in psychology taking place (Littlefield and Johnson 2012; Pickersgill and van Keulen 2012), it was probably just a question of time before moral judgments were investigated in a functional magnetic resonance imaging brain scanner (Greene et al. 2001; Moll et al. 2001). It is noteworthy that many new explanations offered for the processes underlying moral decision-making employed the traditional explanatory pattern contrasting emotion and reason, with an emphasis on the former (Haidt 2007). However, it is important to emphasize the descriptive-normative divide, or the is-ought-problem, respectively, once again: Whereas the philosophers mentioned above debated which psychological faculty we should prioritize in order to make the morally right decision, most empirical researchers interpreted their evidence with respect to the faculties actually underlying the moral decisions their subjects made in a developmental context or an experiment. That is, they tried to explain how moral cognition and behavior works, not what is the morally right thing to do.

However, had the research been restricted to that descriptive question only, just offering an updated scientific account of how people of different kinds make moral decisions under certain circumstances, moral neuroscience might have just become a modernized form of moral psychology, promising to offer better explanations

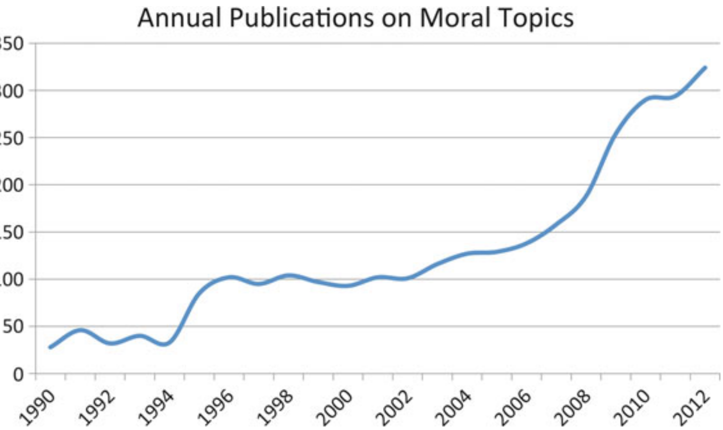

Fig. 7.1 The number of publications in the ISI Web of Science on moral topics was smaller than 50 until 1994, fluctuated around 100 until 2002, and increased steeply since then up to 324. The increase covers all three sub-databases for Social Sciences, Science and Technology, and Arts and Humanities publications. This pattern is not just due to the overall increase of annual publications in the Web of Science with 4.6 million in 2000 up to 7.3 million in 2012 (1.6-fold increase), because the number of publications on moral topics rose from 93 to 324 in the same period (3.5-fold). Method: Topic Search with at least one phrase match of "moral" in combination with any of the following items: judgment, emotion, reasoning, decision, cognition, behavior, and behavior. That is, every publication counted here contains at least one instance of, for example, the phrase "moral cognition" as its topic in the database

owing to its more direct access to the central organ of the mind, the human brain. The seductive allure, from the neuroscientific point of view, and the provocation, from the philosophical point of view, instead consisted in the attempt to cross the border between the descriptive and the normative, for example, by distinguishing morally justified ("rational") intuitions from unjustified ("irrational") ones, based on the brain areas, associated psychological processes, and evolutionary pathways putatively underlying them (Greene et al. 2004, 2008; Singer 2005). Some believed that in the perceived stalemate between different kinds of moral theories, where philosophers sometimes used imagined or actual moral dilemmas to undermine a theory by showing that the assumptions underlying it or decisions following from it are counterintuitive, neuroscience might lend a helping hand.

It probably were such attempts that invited others to critically investigate the explicit or implicit normative presumptions of such arguments (e.g., Kahane 2011), sometimes concluding that the attempts were normatively completely insignificant (e.g., Berker 2009) or, by contrast, identifying genuinely new ways in which moral psychology and neuroscience could and perhaps even should enrich moral philosophy (e.g., Joyce 2008; ▶ Chap. 10, "Psychology and the Aims of Normative Ethics," this section). It goes without saying that some philosophers took the occasion to fundamentally inquire into the meaning of essential concepts of the research such as "moral intuition" (e.g., ▶ Chap. 11, "Moral Intuition in Philosophy

and Psychology," this section). Concurrently, psychologists and neuroscientists questioned the empirical validity of some of the proposed explanations of moral cognition, sometimes re-analyzing or re-interpreting available data (e.g., McGuire et al. 2009; Moll and de Oliveira-Souza 2007), sometimes carrying out improved follow-up experiments (e.g., Moore et al. 2008). Investigating moral cognition has indeed become a diverse and fruitful endeavor attracting empirical as well as theoretical contributions from many disciplines (Waldmann et al. 2012). The following chapters of this section aim to add their share:

The Chapters in this Section

Chelsea Helion and David A. Pizarro, both at Cornell University in Ithaca, NY, USA, start out with a great service to the readers who are not very familiar with the state of the art in moral psychology: In their paper *Beyond dual-processes: The interplay of reason and emotion in moral judgment*, they review many essential developments in that discipline since the late 1990s, that is, the period when psychologists increasingly started to doubt that reason alone accounts for moral judgments. Moreover, experts in the field are likely to profit from engaging with Helion's and Pizarro's argument, stating that psychology's popular dual-process models (Kahneman 2011) and psychologically inspired philosophy do not adequately explain moral cognition. Dual-process models are models that usually distinguish quick, spontaneous reactions, often related to intuition and emotion, from slower, deliberative ones, often associated with reason and cognition.

Discussing the case of disgust in more detail, the authors emphasize that emotion and reason as well as their supposed interaction should not be understood too simplistically: After all, emotional processes are not simply something given that directly influence moral judgment. Rather they are themselves processes that can be regulated and adapted to different situations. Helion and Pizarro criticize that emotion regulation, a process studied intensively in other branches of psychology, has hitherto not been considered sufficiently in research on moral judgment. Depending on the moral context, they argue, people can upregulate or downregulate emotions based on their specific moral beliefs and goals, such as when a vegetarian intensifies his or her feelings of disgust in response to cruelty toward animals. This could explain why people experiencing the same emotions initially might arrive at different moral decisions.

While Helion's and Pizarro's proposal implies that we should beware of simplified psychological and philosophical understandings of emotion and reason and thus makes explanations more complex, it also promises a deeper understanding of moral cognition by drawing our attention not only to the particular circumstances and contexts in which people make moral decisions, but also to their further moral attitudes and beliefs that influence the way in which emotions affect judgments. In contrast to simple models that reduce moral decision-making only to emotion or only to reason and in contrast to dual-process models that take both kinds of processes into account but still presume a clear distinction between them,

Helion and Pizarro conclude that the cognitive cannot be separated strictly from the affective. Although parsimony or simplicity is often considered as virtue of scientific explanations, they cannot be virtuous if they are too reductive to do justice to the phenomena under investigation; it will be interesting to see whether an emphasis on emotion regulation and the complex association between emotion and reason has more explanatory power than other popular accounts within moral psychology and neuroscience.

In a similar way, DaniloBzdok and Simon Eickhoff at the Research Center Jülich together with DominikGroß at the University of Aachen, Germany, provide a service to readers unfamiliar with the scientific literature, but now with a focus on moral neuroscience. After first summarizing several key findings of years of neuroimaging research on moral decision-making, they raise the general question whether the many singular findings of brain areas activated during moral cognition found in previous studies can be integrated into a large-scale network. To answer it, they use a method called Coordinate-Based Meta-Analysis in combination with an activation likelihood estimation algorithm to test for consistent patterns of brain activation across those studies.

Bzdok, Eickhoff, and Groß discuss the results of their meta-analysis particularly with respect to three broad cognitive categories popular in social and cognitive neurosciences, namely, theory of mind, that is, thinking about somebody else's mental states, empathy, and mind-wandering, that is, lying in a brain scanner without any external stimulation. As they show in their paper *The Neurobiology of Moral Cognition: Relation to Theory of Mind, Empathy, and Mind-Wandering*, activation in areas frequently associated with these cognitive categories is often also seen in studies of moral cognition, though to varying degrees. This shows, according to the authors, that there is no dedicated morality module in the human brain, or in their own words, that "no part of the brain is uniquely devoted to moral cognition but this capacity is very likely deployed across several heterogeneous functional domains."

While this finding, simplified to the conclusion that morality, when looking at the brain, is essentially social, may not be surprising to some readers, the authors discuss important experimental and theoretical implications of their results: The suggestion that moral cognition may not be a unified psychological entity raises the question whether there could actually be different kinds of moral cognition that might nevertheless be identified and/or separated in further studies. The diversity on the neuroscientific level could reflect the diversity of the concept of morality itself. Further, their outcome might reveal a general bias in experimental designs used to investigate moral decision-making, often relying on abstract, possibly not very ecologically valid stimuli restricted to moral cognition, not moral *behavior*. Bzdok, Groß, and Eickhoff conclude with a discussion of the meaning of their findings for neuroethics, particularly the descriptive-normative-divide or the is-ought-problem, respectively. They emphasize what we should be careful not to neglect it.

Their general finding is actually reminiscent of Helion's and Pizarro's argument not to underestimate the complexity of moral cognition: Just as it is unlikely that this can be accounted for by only a few basic psychological processes, it is unlikely

that it can be reduced to the brain activity of only a few basic areas. It is an interesting question for further analysis what the brain activity overlap between emotion regulation and moral cognition would look like, a research question involving the expertise of both groups of authors. Surprisingly though, the psychological as well as the neuroscientific review both invite us to reconsider basic questions of what moral cognition actually is and what is the best way to investigate it empirically, basic questions as they are particularly essential to philosophical inquiry, to which we now turn with respect to the next two chapters:

Regina Rini at the University of Oxford, UK, starts out with a service to those who are not very familiar with the scope and aims of moral philosophy: In her paper *Psychology and the Aims of Normative Ethics*, she poses the very general question what normative ethics actually is about, how it is defined. However, just as noted before that there is not only one understanding of "morality," she points out that it is unlikely that there is only one definition of "normative ethics" either. Rini nevertheless identifies three essential questions of that field: First, what a moral agent is; second, which actions are morally permitted or even required; and third, which moral beliefs are justified.

She tries to answer these questions in a dialectical fashion in order to show how moral philosophy can benefit from moral psychology and neuroscience. That is, she starts out with a negative answer why empirical research on moral cognition and decision-making is not relevant to each of the three questions and counters them with a positive rebuttal subsequently, discussing classical sources as well as recent contributions of normative ethics. Rini supports each of her positive answers with instructive examples. Generally, to show that moral psychology or neuroscience has at least some relevance to moral philosophy, it would suffice that she provides a convincing argument in only one of the three cases.

While Rini presents these arguments in favor of the normative significance of the empirical investigation of moral cognition, she concedes that the disciplinary interactions are still at a very early stage and concludes with a number of difficult but important questions for future research: Should it not matter if moral theories demanded something of us that we are psychologically incapable of? Or should this rather motivate us to change our psychological constitution? Would a better scientific understanding of the origins of our moral beliefs undermine their justification and ultimately lead to moral skepticism, the view that *none* of our moral beliefs are justified? In contrast to the humility of her eventual conclusion on psychology and the aims of normative ethics, Rini is quite convinced that psychologists – understood in a broad sense – and philosophers have a lot of work to do together.

Antti Kauppinen at Trinity College, Dublin, UK, contributes his share to that joint work for psychologists and philosophers, in relation to the problem of moral skepticism that Rini briefly refers to in her concluding paragraph. In his paper *Moral Intuition in Philosophy and Psychology*, he investigates whether and under which circumstances moral intuitions may have a justificatory role – but not without first clarifying many of the different possible definitions of "intuition" in philosophy and psychology, particularly when understood as a psychological state.

In a systematic manner, Kauppinen first analyzes different notions of "intuition" in contemporary empirical moral psychology and neuroscience, discussing the dual-process model, the relation between intuition and explanation in the sense that intuitions are understood as proximal causes of moral judgments, that is, that they explain to some extent why we make particular moral decisions, and research suggesting their putative unreliability. He continues, second, with a discussion of the role of intuitions in moral philosophy, namely, two kinds of Intuitionism and Rawlsian Coherentism, and eventually analyzes how intuitions could or could not have a role in justifying these accounts.

Although Kauppinen takes empirical research on moral cognition into account throughout his paper, he particularly devotes his third and last part to a reconciliation of the rather psychological and rather philosophical parts. After emphasizing once again that (moral) intuitions could be quite different things within the different frameworks, he critiques the dual-process model in a way that is reminiscent of Helion's and Pizarro's critique of its simplistic account of emotions, namely, by emphasizing that we should not take intuitions as something that is independent of someone's further beliefs. Indeed, Kauppinen subsequently clarifies the relation between the concepts of "emotion" and "intuition" in the end and summarizes his view regarding the circumstances under which intuitions can play "at least a quasi-foundational role in moral justification."

In the fifth and last paper of this section, titled *The half-life of the moral dilemma task – a case study in experimental (neuro-) philosophy*, Stephan Schleim at the University of Groningen, The Netherlands, carries out a deep analysis of the philosophical as well as the psychological questions that inspired the possibly most popular experiments in moral neuroscience, the moral dilemma task as investigated by Joshua Greene and collaborators (Greene et al. 2001, 2004). With what he calls "The Experimental Neurophilosophy Cycle" he particularly wants to inform those readers not very familiar with experimental research themselves of the translational procedures involved in designing, carrying out, and interpreting this kind of research. With his illustrated "Cycle," Schleim proposes a template for analysis that can ideally be applied to other cases of experimental (neuro-) philosophy as well and that also invites people to reflect on the relation between philosophy and empirical research more broadly.

Central to Greene and colleagues' investigation, Schleim argues, was the psychological puzzle posed by different response patterns to different kinds of moral dilemmas involving the sacrifice of a smaller number of people to save the lives of a larger number, a difference that was in the end explained by differences in emotional responses – reminiscent of what Kauppinen called "proximal causes" – and even used to undermine the justification of some kind of moral theories while supporting that of others, in particular utilitarianism. However, as Schleim argues, these interpretations presume a couple of intermediary steps, such as a choice of experimental procedures and methods, carrying out the actual experiment, preprocessing and analyzing data, and interpreting them in a psychologically significant way, making use of inferences to the best explanation. Just as the

strength of a chain depends on the strength of its individual links, the strength of the whole "Cycle" depends on the strength of its constitutive parts.

In his conclusion, Schleim notes that in light of his neurophilosophical analysis, philosophers need not fear to lose their jobs due to the explanatory power of cognitive neuroscience, as once was suggested in a report accompanying the original publication of the moral dilemma task study. By contrast, just as it is the case with respect to philosophy of science in general, philosophers and scientists alike can – and perhaps even should – engage in a critical philosophy of experimentation to emphasize the individual choices, experimental limitations, and backgrounds of explanatory patterns to better understand the scope of the research and in particular the strength of the translational links connecting philosophy, psychology, and neuroscience.

Possible Implications for Applied Ethics

From the perspective of neuroethics, the topic of this section is very abstract and theoretical and some may wonder whether it may have any implications for applied (neuro-) ethics at all. Although it is interesting in itself to understand how moral cognition, an essential human capacity, works and although the answers to this question may influence our understanding of what it means to be human, it is conceivable that the research might become relevant to a couple of applied questions, as the following examples are intended to show:

First, informed consent is an important issue in medical ethics and practice in general; it might be a particular challenge in the case of neurological or psychiatric/psychological disorders where the central decision-making structure may be impaired (Northoff 2006). Thus, finding out what the necessary and sufficient structures are for moral cognition may help to understand when a subject still is or is no longer capable of making an informed decision in a morally salient situation such as agreeing to undergo a potentially painful and risky medical treatment, perhaps even more so in cases where subjects are so much impaired that they cannot communicate any more in a normal manner, such as in a minimal conscious state (Jox et al. 2012). The issue of informed consent might be particularly problematic when the cognitive-emotional capacities required for it are precisely the target of the intervention and will only be sufficiently restored after the treatment.

Second, clinically as well as nonclinically, the bodily functions underlying moral cognition might themselves become a target of diagnosis and intervention. For example, in the history of psychiatry, some mental disorders, particularly psychopathy, had a moral connotation or were (and sometimes still are) understood as a moral disease (Werlinder 1978). The moral skills of psychopaths are a common topic of scholarly debate (Kennett and Fine 2008; Levy 2007; Sauer 2012), and it is very likely that there will be more research within moral psychology and neuroscience on that disorder. Already now, efforts are made to diagnose or identify psychopaths by means of brain scanners (Anderson and Kiehl 2012) and also to

screen and intervene (Rose 2010), that is, to treat them with the aim of curing their alleged moral deficits. It has even been discussed under which conditions research on psychopaths' psychological capacities might influence current legal practices of responsibility and legal insanity, emphasizing the emotional aspect prevalent in the moral neuroscience literature (Morse 2008). Besides the question whether this will ever be feasible, it goes without saying that the possibility of such interventions, affecting the deep core of someone's personality, needs critical discussion by ethicists, medical experts, and those primarily affected by the decisions alike.

However, even those who are not considered to be morally impaired might once be confronted with the option of intervening in the bodily functions underlying moral cognition, namely, third, as a form of moral enhancement (Douglas 2008). The previously mentioned moral dilemma task was actually already used in experiments to test whether subjects, when under the influence of a psychopharmacological substance like a selective serotonin re-uptake inhibitor, make "better" moral decisions than a control group treated with placebo (Crockett et al. 2010). It may be just as difficult as in the formerly mentioned case of moral treatment to find a means of moral enhancement that works, especially outside of a protected laboratory environment, and to agree on what a better moral decision would be in the first place. It goes without saying that any such attempts would have wide social ramifications.

Fourth and finally, it should not be forgotten that many moral psychologists, particularly those who carried out their research from a developmental point of view, developed ideas on improving moral education generally (Kohlberg 1984; Lind et al. 2010). If moral neuroscience truly adds to our understanding of moral decision-making, the developmental and situational conditions under which it functions, then we might expect this knowledge to contribute to the traditional pedagogical aim. This would not have to be restricted to pupils and students, but might even include preventive training to anticipate and avoid moral failure in governmental or private institutions.

As stated above, moral cognition as a research topic is abstract and theoretical, involving many conceptual as well as experimental challenges (Waldmann et al. 2012). However, this short and certainly preliminary list shows that there are related applied issues as well, some of which will probably increase in relevance as the field develops further. The last point for consideration mentioned here is the public as well as scholarly communication of the results, which often suggested that our moral decisions are made arbitrarily, that spontaneous emotional or intuitive responses may mislead us, even that we can be morally "dumfounded," that is, that we tend to cling to a judgment once made even after we learned that the reasons usually justifying this judgment do not apply in this particular instance. A popular case reported by Jonathan Haidt was an (imagined) example of incest that excluded all of the usual counterarguments, such as coercion, minority, or the increased risk of ill offspring, that people still considered as morally inappropriate after it had become clear that their justifying reasons do not apply in the presented case (Haidt et al. 1993).

However, other psychologists have warned that the widely disseminated findings of what John Kihlstrom called the "people are stupid" school of psychology,

presenting our decisions as emotionally driven, not based on reasoning, irrational, blinded by egoistic interests, and easily manipulated in experimental settings may constitute a limited and one-sided scientific account of what people are like (Kihlstrom 2004; Turiel 2010). The papers in this section emphasize that many central notions and experimental designs are preliminary; therefore, their results and interpretations are preliminary, too. Furthermore, much of the research is based on the subjects' trust in the experimenter, subjects who are often medicine, psychology, or neuroscience students and sometimes even participate in their own professors' experiments for mandatory course credit. The rational decision these subjects make is to actually participate in these experiments, in which they are often not informed or perhaps even misled about the experiments' aim – for otherwise the experimental manipulation might not work anymore. The behavior they subsequently show is also a function of the way the experiment is designed. The papers in this section suggest that there may be more than just one account to be told about what people are like, particular with respect to their moral cognition.

Acknowledgments I would like to thank Michael von Grundherr, Felix Schirmann, and Steffen Steinert for helpful suggestions to improve a previous version of this chapter.

Beyond Dual-Processes: The Interplay of Reason and Emotion in Moral Judgment

Abstract

A great deal of research in moral psychology has focused on the interplay between emotion and reason during moral judgment, characterizing the two as forces working in opposition to influence judgment. Below, recent psychological research on morality is reviewed, with a special focus on disgust and the nature of its role in moral and political judgment. Behavioral, neuroscience, and physiological data are reviewed looking at the role of disgust in moral judgment, with a particular emphasis on the role of emotion regulation – the process of shifting emotional responses in order to meet one's goals. It is suggested that dual-process theories of moral judgment are not well suited to understand the role of emotion regulation in influencing moral judgments and decisions. Theories that emphasize the primacy of one process over another may ultimately be missing the complexity how these processes interact to influence moral judgment.

Introduction

> It was on the moral side, and in my own person, that I learned to recognize the thorough and primitive duality of man; I saw that, of the two natures that contended in the field of my own consciousness, even if I could rightly be said to be either, it was only because I was radically both
> -Robert Louis Stevenson 1886, p. 56

Stevenson's classic 1886 novel "The Strange Case of Dr. Jekyll and Mr. Hyde," tells the tale of Dr. Jekyll, a man who wants to end the struggle between good and evil within him. In order to do so, he formulates and ingests a potion designed to split his mind into two – one personality to house his baselessness and immorality (Mr. Hyde), and one to house the morally pure traits he values most. The inner conflict that humans experience between their moral selves and their more unrestrained, egoistic selves has been a consistent theme in literature for centuries. While (largely) discarding the good-versus-evil aspects of this dichotomy, moral psychology has nonetheless embraced the basic division of mental processes into two general types – one mental system that is cold, rational, and deliberative, and another that is emotional, intuitive, and quick. This characterization has served as a basic organizational framework for understanding the processes involved in human judgment across a variety of domains, including moral and ethical judgments (e.g., Kahneman 2011). This "dual-process" approach to the mind has motivated a great deal of research on moral judgment within the last decade, and has led psychologists to reconsider the historically dominant approaches to moral judgment, approaches which emphasized the primacy of reason. But the division of the mind into two systems, while fruitful, has encouraged researchers to characterize emotion and reason as forces acting upon moral judgment in opposing directions, and to focus on factors that give rise to the dominance of one over the other. This chapter will focus on a particular emotion – disgust – in order to illustrate that the simplicity of the dual-process approach may hide some of the more nuanced ways in which emotion and reason interact to produce moral judgment and behavior. In particular, it will highlight research on emotional regulation as an example in which reason guides emotion rather than battles against it. Taken together, these two bodies of research suggest that characterizing reason and emotion as separate, opposing forces in moral judgment is a caricatured description of two processes that often interact in complex ways to motivate judgment and action (Pizarro 2000).

The Dethroning of Reason

For the majority of the twentieth century, psychologists viewed decision making as a "cold" process in which individuals calmly and rationally weigh pros and cons to arrive at a decision that maximizes their utility (Loewenstein and Lerner 2003). Research in moral psychology echoed this emphasis on reason: Early studies of

moral judgment[1] focused on the importance of cognitive abilities across development, and on how the emergence of specific abilities shaped the child's understanding of moral rules (Kohlberg 1963; Piaget 1932). As individuals matured, they would approach a higher "stage" of moral thinking, and while many would never reach the highest stages of moral reasoning, the majority of individuals would reach a stage of moral sophistication required to uphold the norms and laws of a functional society.

However, as research on emotion grew, it began to transform the behavioral sciences, and the study of judgment and decision making in particular. No longer was judgment characterized as a "cold" emotionless process, but as infused with emotion at every turn. In an influential paper, Haidt (2001) built upon this emerging affective science, and applied it to moral judgment by making a radical claim – that reason played a much smaller role in ethical and moral judgment than psychologists thought. Taking a note from the philosopher David Hume (1777/1960), Haidt argued that intuitions (often in the form of emotional responses) were, in fact, the primary causes of moral judgment. In what he dubbed "social intuitionism," Haidt proposed that when individuals are faced with a moral question (e.g., "Julie and Mark are a brother and sister that had consensual sex"), and are asked to make a moral judgment ("How morally wrong was Julie and Mark's behavior?"), it is their experience of emotion (in this example, disgust) that gives rise to the moral judgment ("What Mark and Julie did was wrong!"), not their ability to formulate reasons. Notably, in examples like this, individuals are actually at a loss to justify their moral judgment and become "morally dumbfounded" – reduced to offering something like "it is just gross" as their only reason for their judgment.

For Haidt, ethical judgment is a great deal like aesthetic judgment: It is made quickly, effortlessly, and without a great deal of conscious deliberation (Greene and Haidt 2002). More radically, Haidt claimed that if deliberate reasoning played a role at all in moral judgment, it was most likely as a post hoc attempt to justify an individual's intuition-driven moral judgments (Haidt 2001; Haidt and Bjorklund 2008). As support for his claim, Haidt also drew on growing evidence from social psychology, demonstrating the power of nonconscious influences on judgment, as well as from cross-cultural research showing that cognitive-developmental theories (such as that of Kohlberg) did a poor job at predicting moral judgments in non-Western cultures (Haidt et al. 1993; Shweder et al. 1997).

Haidt's social intuitionist model happened to coincide with a new approach to study morality pioneered by Greene and his colleagues, who paired modern neuroimaging techniques with classic philosophical moral dilemmas to arrive at a similar conclusion – that emotions played a much larger role in moral judgment than previously thought. Greene and colleagues (2001) demonstrated that when faced with classic sacrificial moral dilemmas (in which one individual must be

[1]Notably, some early researchers suggested that children's morality was largely emotionally driven (Wendorf 2001; Kline 1903). The insights from this approach were all but lost in the coming dominance of the cognitive-developmental approach.

sacrificed to save a greater number of people), individuals often responded in a manner consistent with their gut, emotional reactions, and argued that this could be seen in the patterns of neural activation observed while individuals were reading emotionally evocative dilemmas. However, when given enough time to deliberate, individuals could overturn their initial gut reactions and reply with a more calculating (i.e., utilitarian) response. Yet for both Greene and Haidt, the emphasis was on the divided mind – one system that produces an initial moral judgment, and another capable of intervening occasionally to alter the judgment. While these approaches were influential in shifting moral psychology away from the historically dominant rationalist theories' of moral judgment, the pendulum swung swiftly in the direction of emotional primacy – the view that reasoning played little or no role in most moral judgments. Indeed, combined with the research emerging in other areas of judgment and decision making, it seemed fairly obvious that human judgment was driven if not solely, at least primarily, by emotional and nonrational processes (Bargh and Ferguson 2000).

Yet a number of more recent findings have demonstrated that reason is not as inert as these accounts (or, at least, the stronger versions of these accounts) implied. For instance, there is evidence that simply temporarily encouraging rational thought can have a demonstrable effect on moral judgment. Researchers recently demonstrated that engaging in a cognitively challenging task prior to making a moral judgment can cause individuals to go against their initial intuitive moral judgment when responding to moral dilemmas (Paxton et al. 2011). In addition, when given sufficient time to deliberate, individuals are more likely to be persuaded by reasoned arguments that a seemingly wrong, yet harmless act was not, in fact, immoral (Paxton et al. 2011).

Encouraging individuals to adopt a rational mindset can lead them to make judgments of moral blame that go against their intuitive initial reaction. For instance, individuals intuitively reduce their judgments of blame for harmful acts that were intended, although the causal link between the intention and the harm occurred in an unexpected fashion (Pizarro et al. 2003). However, when instructed to think rationally and deliberately, individuals become insensitive to extraneous information about the causal link and focus on the intention of the actor and the harmful outcome. In other words, a simple prompt to respond rationally is enough to shift the nature of moral judgment toward answers that are more careful, deliberate, and free of normatively extraneous information.

One final source of evidence for the ability of reason to influence moral judgment comes from research demonstrating that the likelihood of engaging in moral reasoning changes based on cognitive resources available to the individual at the time the moral judgment is made. Occupying an individual's mind with a task (i.e., placing them under "cognitive load") has been shown to interfere with the moral reasoning process, with individuals under load more likely to favor intuitive moral decisions (Greene et al. 2008). Cognitive load can also derail the moral justification process, reducing the likelihood that individuals will rationalize their own immoral behavior (Valdesolo and DeSteno 2008). The corollary of this evidence is that, in the absence of constraints on the ability to deliberate, individuals are indeed making

use of careful deliberation when arriving at moral judgment. In short, there is plenty of evidence that individuals can (and do) engage in moral reasoning when motivated or prompted to do so.

Yet even research emphasizing the influence of reason adheres to a fairly simplistic dichotomy pitting reason against emotion/intuition. This may be because researchers tend to utilize methods designed to pit one process against the other, or that favor one process over the other (Monin et al. 2007). The answers to emerge from these methods will, by design, seem as evidence for or against one side of the dichotomy. For instance, Kohlberg's (1963) methodology involved presenting participants with moral dilemmas that pit two equivalent courses of action against each other, and to ask participants to verbally justify their decisions. When presented with the famous "Heinz" dilemma (in which participants must determine if it is better for Heinz to steal an expensive medicine in order to keep his wife from dying), participants are not only asked to determine which is the better decision, they are also asked detailed questions about their reasoning process. In its explicit prompting of reason, and in its use of dilemmas with equally compelling courses of action, any researcher would conclude that reasoning is at the heart of moral judgment (Monin et al. 2007).

On the other hand, researchers who favor emotional/intuitive accounts of moral judgment often ask participants to evaluate the moral infractions committed by others, frequently focusing on extreme scenarios involving bestiality, child pornography, and incest (for reviews see Pizarro and Bloom 2003; Monin et al. 2007). Unlike the Kohlbergian dilemmas, these moral scenarios create a strong, immediate affective reaction (and are not "dilemmas" in the traditional sense of the word, since one course of action seems clearly worse than another). Faced with such scenarios, participants rarely need to deliberate about competing moral principles in order to arrive at a judgment. Moreover, rather than being asked to reason aloud to justify their moral judgments, participants are generally asked to assess moral wrongness after the putative moral infraction has been committed (rather than to debate the possibilities for a future course of action). These kinds of reaction-focused questions tend to stack the deck in favor of an emotion-based account of moral judgment.

Despite these methodological limitations, however, there is still a great deal of evidence pointing to a more complex interrelation between reason and emotion/intuition. Perhaps shifting the question from simply asking if reason influences moral judgment, and toward *when* and *how* reasoning influences moral judgment yields more nuanced insight. Take one example of a more subtle interaction between reason and intuition – studies of expertise have shown that a learned process can be made intuitive over time (Zajonc and Sales 1966). Similarly, moral intuitions themselves may arise from prior instances of moral reasoning. A person may reason their way to a particular moral view (such as that animals should not be killed and eaten, or that slavery is wrong), and over time, this moral view becomes intuitive (Pizarro and Bloom 2003). The mechanism by which a reasoned choice may become an intuition is, unfortunately, not well-captured in a dual-process approach that does not take into account the ways in which intuition and reason interact over time.

Disgust and Moral Judgment: A Brief Overview

When it comes to the regulation of human behavior, many moral codes extend far past the concerns over harm and justice that have traditionally been the focus of the cognitive-developmental tradition in moral judgment. A growing body of work has demonstrated that moral codes emphasize a number of other domains – respect for authority, group loyalty, and purity. For instance, large sections of the Bible, Koran, and many other religious texts focus on the importance of keeping oneself clean in body and in spirit (Haidt et al. 1993; Shweder et al. 1997). The motivational fuel that enforces moral norms across these domains appears to be emotions such as anger, empathy, contempt, guilt, shame, gratitude, and (of particular relevance to this discussion) disgust (Rozin et al. 1999; Decety and Batson 2009; Lazarus 1991; Trivers 1971).

Disgust – an emotion that likely evolved to prevent individuals from coming into contact with dangerous pathogens – has recently been strongly linked to moral, social, and political judgments (Schnall et al. 2008; Inbar et al. 2009a, b). A great deal of research has been conducted in the past two decades in an attempt to classify when, where, and to whom disgust is expressed (Haidt et al. 1994; Rozin et al. 2000; Olatunji et al. 2008; Tybur et al. 2009). It has become clear that disgust is strong, easy to induce, and provides immediate motivation to avoid the target of disgust. There also appear to be a set of near-universal elicitors – bodily and animal products such as feces, urine, vomit, and rotten meat (all potential transmitters of pathogens) seem to elicit disgust in most people. In addition, often all it takes is a single picture or word to make an individual feel full-blown disgust. In this sense, it is one of the least "cognitive" emotions – it can often seem more like a reflex.

Research on individual differences in disgust has also shed light on the nature of disgust elicitors. The most widely used measure of individual differences in disgust is the Disgust Sensitivity Scale (DS-R; Haidt et al. 1994, modified by Olatunji et al 2007). This scale divides disgust into three unique sets of elicitors: core, animal reminder, and contamination disgust. A more recent scale proposes a different set of subdomains of disgust: pathogen disgust, sexual disgust, and moral disgust (Tybur et al. 2009). The authors suggest that each facet of disgust fits a specific evolutionary function: Pathogen disgust (analogous to core/contamination disgust) is meant to protect an individual from disease, sexual disgust is meant to protect an individual from actions that would stand in the way of one's evolutionary fitness (e.g., incest, individuals that one does not find aesthetically or histologically attractive), and moral disgust is meant to protect an individual from those that would hurt the success of the individual or the group (such as acts of selfishness). Nonetheless, both scales emphasize the fact that disgust appears to be a response to potential contamination from a substance, individual, or action.

While disgust may not be the most relevant moral emotion, nor even the most common, disgust is focused on because the wealth of research on this emotion helps shed light on a more general point – that the interaction between reason and emotion in moral judgment is far more complex than one might expect (Pizarro et al. 2011). A great deal of evidence accumulated in the last decade suggests that

disgust easily extends its influence to the sociomoral domain – individuals use disgust terminology to describe both the revolting and the reviled (Rozin et al. 2008). While it may have originated as an emotion meant to keep us from ingesting something dangerous, it now seems to motivate us to keep away from individuals or entire social groups, and to evaluate a certain kind of act as morally wrong. For instance, feeling disgust at the time of moral judgment increases the severity of a moral judgment – people think that an act is more wrong, and that an individual is more blameworthy – even when the source of disgust is completely unrelated to the target of judgment (Schnall et al. 2008). While Schnall and colleagues (2008) found a domain-general increase in moral severity, recent research has shown that feeling disgust may play an especially strong role in moral judgments having to do with *purity*, acts seen as wrong not because of their direct harm but because of their symbolic degradation or contamination of the self or society. Feeling disgust in response to purity violations (such as consensual incest) has been linked to more severe punishment for moral transgressors (Haidt and Hersh 2001).

Indeed, disgust is especially powerful in influencing judgments in the domain of sexual mores. Inbar, Pizarro, Knobe, and Bloom (2009b) found that people who are more easily disgusted (as measured by the "disgust sensitivity" scale; Olatunji et al. 2007) have more negative implicit attitudes about homosexuality. Echoing this, individuals who are easily disgusted are more likely to show negativity toward homosexuals, but not toward other out-groups such as African-Americans (Inbar et al. 2012b; Tapias et al. 2007). In addition, inducing disgust increases people's explicit and implicit bias against homosexuals (Dasgupta et al. 2009; Inbar et al. 2012b).

Individual differences in the tendency to feel disgust (i.e., *disgust sensitivity*) has also been linked more generally to political conservatism, specifically in political issues related to purity and divinity – such as abortion and gay marriage (Inbar et al. 2009a, 2012a). This is consistent with work showing that liberals and conservatives rely upon different kinds of moral intuitions for their judgments – liberals rely on assessments of harm and fairness when making moral judgments, whereas conservatives also rely on purity, loyalty, and authority (Graham et al. 2009). Indeed, simply reminding people that there is disease in the environment (consistent with the motivation induced by disgust) can lead individuals to temporarily report being more politically conservative (Helzer and Pizarro 2011).

One of the more interesting ways in which disgust has been implicated in moral judgment comes from work on what some researchers have dubbed "moralization." Within a generation (and perhaps not even that), we can observe concrete changes in societal views concerning the morality of certain acts. For instance, while in the 1960s, smoking was ubiquitous, today, smoking is confined to select areas, smokers are shown the door and asked to partake elsewhere, and morally judged for their behavior (Rozin 1999). How did a behavior like smoking – which was so commonplace 50 years ago – become moralized over time? Rozin (1999) implicates disgust in this process of moralization – bringing a behavior that was previously seen as non-moral into the moral domain. Rozin and Singh (1999) showed that the targets

of moralizing disgust can even change across one's life span. They surveyed college students, their parents, and grandparents, and found that all three groups reported being equally as disgusted by and expressive of negative attitudes toward cigarette smoking, even though the grandparents indicated that they had grown up in an age that was more tolerant toward cigarette smoking.

Researchers are increasingly learning about the neural and physiological correlates of disgust. Experiencing and recognizing disgust has been linked to activation in the anterior insula and putamen (Moll et al. 2002; Calder et al. 2000); however, this relationship is not consistently found across all disgust studies that utilize neuroimaging techniques (Phan et al. 2002). Disgust has also been associated with greater facial muscle tension, both increased and decreased heart rates, and increased skin conductance (Demaree et al. 2006). Olatunji and colleagues (2008) found differences in the physiological reactions between different kinds of disgust: Core and contamination disgust (such as the disgust over rotten meat, or at sipping out of a stranger's beverage by mistake) were associated with increased facial muscle tension and heart rate while watching a video of an individual vomiting, and watching a video and having blood drawn, was associated with higher facial muscle tension and *decreased* heart rate in individuals sensitive to "animal reminder" disgust (disgust related to gore, body-envelope violations, and dead bodies).

Emotion Regulation: The Intersection of Reason and Emotion

Knowing how disgust works to influence moral, social, and political judgments is informative, but it paints an incomplete picture of how emotions (like disgust) influence individuals over time. A key limitation of many studies on emotion is that they do not take into account the various strategies individuals employ in everyday life to either avoid feeling certain emotions, feel them less strongly, or feel them more strongly. In fact, it is fairly evident that individuals engage in this sort of emotional regulation fairly frequently (Gross 2002). This regulation is necessary, in part, because the environment in which emotions evolved is in many ways quite dissimilar to the current environment, making emotional responses in the modern world poor guides to achieving goals (Tooby and Cosmides 1990; Gross 1998a). This ability to regulate emotions allows, more generally, for a rich interaction between an individual's long-term, deeply valued goals and her short-term emotional reactions. In the case of moral judgment, the need for emotional regulation should be clear – individuals often need to alter their emotional states to coincide with their moral goals.

Researchers investigating the regulation of emotion have proposed five different categories of emotional regulation (Ochsner and Gross 2008): (1) *situation selection* – selecting situations that are conducive to attaining one's goals or to avoid ones that are not (for example, a married man declining an invitation to grab a drink with an ex-girlfriend), (2) *situation modification* – taking steps to alter one's current situation to bring it in line with one's goals (if the man does accept the invitation,

choosing to talk about his happy marriage instead of reminiscing about the past relationship), (3) *attentional deployment* – focusing one's attention on something else (choosing to focus on how gray his ex-girlfriend's hair has become rather than on her ample cleavage), (4) *cognitive change* – changing one's emotional understanding of the situation at hand by cognitively reappraising features of the situation (reframing the situation as catching up with an old friend rather than drinking with a former lover), and (5) *response modulation* – regulating the physiological response of an emotional state while it is currently being experienced (the man telling himself that his sweaty palms are due to the crowded bar rather than to any feelings of attraction). The first four components of emotional regulation have been referred to as *antecedent-focused* regulation strategies, and the fifth is referred to as a *response-focused* regulation strategy (Gross 1998b).

Previous research has indicated that regulating negative emotions, and specifically disgust, can have downstream cognitive and physiological consequences. Multiple studies have asked participants to adopt an antecedent-focused (e.g., reappraisal) or response-focused (e.g., suppression) regulation strategy, and have demonstrated that each makes different contributions to altering one's emotional experience. Gross (1998b) had participants watch a disgust-eliciting video, and found that though both reappraisal and suppression reduced disgust-expressive behavior, reappraisal decreased ratings of subjective disgust while suppression had no effect on subjective disgust, and was instead linked to increased activation of the cardiovascular system. Recent research has demonstrated that this type of reappraisal process can be automated via the use of implementation intentions – regulatory strategies that take the form of an if-then plan – and that different implementation intentions can affect what aspect of the disgust experience is regulated (Schweiger Gallo et al. 2009; Gallo et al. 2012). Gallo and colleagues (2012) had participants form either a goal intention ("I will not get disgusted!"), an antecedent-focused implementation intention ("I will not get disgusted, and if I see blood, I will take the perspective of a physician!"), or a response-focused implementation intention ("I will not get disgusted, and if I see blood, I will stay calm and relaxed!") before reporting on valence and arousal while viewing a series of disgusting and non-disgusting images. They found that individuals who had formed an antecedent-focused implementation intention reported that the disgusting images were significantly less negative, but that there were no differences between this group and the goal-intention group on reported arousal, suggesting that this antecedent-focused strategy was changing the meaning of the emotional experience without altering the physical experience. Individuals who had formed a response-focused implementation intention reported significantly less arousal when viewing disgusting images as compared to the other two groups; however, there were no differences between this group and the goal-intention group on assessments of valence. Taken together, these studies suggest that different emotion regulation strategies can alter different components of the emotional experience. Within the moral domain, it remains unclear what aspects of disgust experience (valence, arousal, appraisal) working alone or in tandem contribute to moral judgment, and using different antecedent- or response-focused strategies to regulate disgust may help illuminate this process.

The Neuroscience of Emotion Regulation

We now know a great deal more about the neural underpinnings of emotion regulation, and how emotion and reason interact within the brain. For instance, a study that used functional neuroimaging to look at different regulatory strategies showed that emotional suppression and reappraisal work on different time courses, specifically showing that when asked to regulate disgust, reappraisal was linked to increased activation in prefrontal areas (the medial and left ventrolateral prefrontal cortex – areas associated with cognitive control) during early stimulus presentation, and was correlated with decreased activity in regions known to be implicated in affective responses (left amygdala and insula) during the later stages of stimulus presentation. Emotional suppression showed a distinctly different pattern, and was linked to activation of prefrontal control areas during the later stages of stimulus presentation, accompanied by increased amygdala and insula responses (Goldin et al. 2008). This suggests that different regulatory strategies may play out over a different time course, and that they have a differential impact on the subjective, physiological, and neural components of an emotional experience.

A great deal of research has implicated the prefrontal cortex (PFC), a region associated with volition, abstract reasoning, and planning, as playing a primary role in the process of emotion regulation (Ochsner and Gross 2005; Wager et al. 2008). Emotion regulation appears to engage multiple areas of the PFC, including the dorsolateral prefrontal cortex (dlPFC), the ventrolateral prefrontal cortex (vlPFC), and the dorsomedial prefrontal cortex (dmPFC) (Ochsner and Gross 2005). In addition, research suggests that successfully reappraising emotional stimuli involves both cortical and subcortical pathways, roughly illustrating that the process recruits areas of the brain associated with "cognitive" and "affective" processes (Wager et al. 2008). For instance, the amygdala, a subcortical structure heavily implicated in affective responses, plays an integral role in the processes of guiding attention to and forming evaluations of affective stimuli (Ochsner 2004). The amygdala's detection of affective stimuli can happen rapidly and can even occur non-consciously (Amodio and Devine 2006). Further supporting its role as a key player in emotional regulation, amygdala activation and deactivation has been linked to the augmentation and reduction (respectively) of an affective response (Ochsner and Gross 2005). Other affective brain regions involved in emotional regulation include the ventral striatum, the mid-portion of the cingulate cortex, and the insula – an area that has been implicated in the subjective experience of disgust and has been of particular importance in linking disgust with moral judgment (Lieberman 2010).

A greater understanding of the interactions between affective brain regions and higher cognitive brain regions during emotional regulation may help shed light on both the psychology of regulatory behavior and on an understanding of how emotion regulation may inform moral judgment. A great deal of research in emotion regulation and neuroimaging has focused on cognitive reappraisal, an antecedent-focused regulation strategy that involves reframing emotionally evocative events. Many of these studies involve presenting participants with aversive

images during a functional MRI scan, while giving them instructions on how to view the image in ways that may encourage the up- or down-regulation of their emotional response. Using this method, Wager and colleagues (2008) demonstrated that cognitive reappraisal relies on a bidirectional relationship between affective and cognitive regions. They found that the cognitive reappraisal of emotion involves the successful recruitment of areas associated with memory, negative affect, and positive affect/reward. Specifically, they found that the relationship between the left vlPFC (an area involved in higher cognition) and reappraisal success involves two mediating pathways: (1) a path which predicts reduced reappraisal success involving areas involved in negative emotion, such as the amygdala, lateral orbitofrontal cortex (OFC), and anterior insula, and (2) a path predicting increased reappraisal success involving areas implicated in positive affect/reward, such as the ventral striatum, the pre-supplementary motor area (SMA), the precuneus, and subgenual and retrosplenial cingulate cortices. The positive association between left vlPFC activation and the activation of both of these networks suggests that the left vlPFC plays a role in both the generation of (path 1) and regulation of (path 2) negative affect during cognitive reappraisal.

In short, the ability to successfully regulate emotion relies on structures implicated in the generation of both negative and positive affect, as well as on the same structures being able to both reduce negative appraisals and generate positive ones. What this suggests is that the regulatory strategy of cognitive reappraisal has properties that overlap significantly with both systems – affective and cognitive. This echoes a claim made by Pizarro and Bloom (2003), who pointed to the importance of cognitive appraisals in guiding moral responses that are typically described as emotional. Taken together, this research suggests that the emotional reactions that accompany a moral evaluation can be regulated via cognitive reappraisal, allowing for a great deal of flexibility on the influence that emotions (like disgust) play in the formation of moral judgments.

This bidirectional relationship between emotion and cognition makes sense within the context of moral judgment. In the classic trolley dilemma, an individual is asked to imagine that they are a trolley car operator and that a runaway trolley is hurtling down the track (Foot 1967; Thomson 1985). The trolley has to go on one of two diverging tracks: (1) a track where five people are working and (2) a track where one person is working. In a typical moral psychology experiment, participants are then asked about the permissibility of killing one to save five. Using this dilemma, Greene and colleagues (2001) uncovered the role of emotional engagement in moral judgment. To manipulate emotional engagement, participants were presented with two versions of trolley-style dilemmas: (1) In the *impersonal* version, participants are told that they can hit a switch that will put the trolley onto a different track, where it will only hit one person, (2) In the *personal* version, participants are asked to imagine that they are standing next to a large stranger on a footbridge that goes over the trolley tracks, and if they push the stranger, the trolley will stop, thus saving the five people.

The researchers found that increased emotional engagement (personal vs. impersonal) elicited greater activation in regions of the brain that had been implicated in affective processing (the bilateral medial frontal gyrus, the bilateral posterior cingulate gyrus, and the left and right angular gyrus). In the impersonal moral condition, they observed significantly more activation in regions associated with working memory (the right middle frontal gyrus, the left parietal lobe, and the right parietal lobe). Greene and colleagues (2004) extended this result, and showed that participants exhibited greater activation in the amygdala when they are resolving personal moral dilemmas than when they resolving impersonal moral dilemmas. During the personal moral dilemmas, participants also exhibited increased activation in brain regions implicated in theory of mind processes: the medial prefrontal cortex (mPFC), the precuneus, the posterior superior temporal sulcus (pSTS), and the temporoparietal junction (TPJ). The researchers used this as evidence to make the claim that personal moral dilemmas are more affectively charged, and further suggest that personal moral dilemmas involve a network that focuses attention away from the "here and now" and instead directs attention to predicting future events and considering the mental states of others (Greene 2009). More recent work has modified the impersonal/personal distinction, instead focusing on psychological and neural differences between deontological judgments (which some have posited are automatic responses driven by emotion) and utilitarian or consequentialist judgments that some claim are the product of conscious moral reasoning (Greene 2009; Greene et al. 2008). Nonetheless, the revised distinction retains the distinction between "emotional" and "cognitive" processing that gives rise to different kinds of moral judgments.

Though the existence of two distinct systems is a plausible account for the observed pattern of results, reconciling this work with research in emotion regulation perhaps prompts a slightly different description regarding the processes involved in guiding these sorts of judgments. Rather than characterizing judgment as driven by two opposing processes fighting over which answer is morally correct, these dilemmas are prompting individuals to reconcile their affective responses with their moral goals through the regulation of their emotional reactions. Though we tend to think of the typical instance of emotional regulation as the down-regulation of an emotional response, there are times when individuals up-regulate their affective responses in order to meet their goals. Within the moral domain, this is particularly the case for empathy, where taking the perspective of another is often accompanied by increased emotional arousal for the self (Batson 1998). The personal and impersonal versions of the trolley dilemma may just as easily be described as involving cognitive appraisals that facilitate the up- and down-regulation of emotional experiences, and that those who are able to regulate their emotions effectively are able to suppress or increase the affective response that they view as appropriate for the dilemma at hand.

One source of evidence for the importance of such up- and down-regulatory strategies comes from research demonstrating that manipulating the self-relevance of emotional stimuli (akin to the personal/impersonal distinction in the moral research) can influence one's affective experience (Ochsner et al. 2004). In one

study, participants were asked to up- or down-regulate their emotions using a self-focused reappraisal strategy (i.e., to think about the personal relevance of each image as it appeared). For example, if participants were shown a picture of a gruesome car accident, participants were asked to either imagine themselves or a loved one in the negative situation (up-regulation) or to think of the situation from a detached third-person perspective (down-regulation). Participants reported that down-regulating emotion was significantly more difficult than up-regulating emotion. In addition, amygdala activation was modulated by reappraisal, with up-regulation being linked to increased activation in the left amygdala and down-regulation was linked to bilateral amygdala deactivation.

This self-focused reappraisal strategy may be analogous to the personal/impersonal moral distinction, in which individuals are asked to put themselves in the situation of physically pushing a man to his death or to physically distance themselves from the event by imagining themselves flipping a switch. Asking participants to imagine themselves causing or being personally involved in a situation is similar to a self-focused up-regulatory strategy, whereas asking participants to imagine pushing the button is a self-focused down-regulatory strategy. Thus, it seems possible that the differences observed in the personal/impersonal moral dilemmas may reflect the effects of up- and down-emotion regulation, rather than the workings of two distinct processes. This would be consistent with the suggestion that individuals who favor utilitarian solutions to affectively charged sacrificial dilemmas are either simply less likely to feel a negative affective reaction to the dilemma in the first place, or are able to down-regulate their negative emotional reactions in order to meet their utilitarian moral goals (Bartels and Pizarro 2011).

Conclusion and Future Directions

The most plausible approach regarding the processes involved in emotion regulation, especially, we think, in the domain of moral judgment, is what researchers have termed an "instrumental" account of regulation. This account breaks from the tradition of straightforward psychological hedonism – the view that individuals are always motivated to feel positive emotions and minimize negative emotions – and instead suggests that emotion selection and regulation can be described as maximizing the utility of a particular goal, even if the goal is best served by feeling a negative emotion (Tamir 2009). Certain emotions may be more useful in some contexts than others – while pleasant emotions may be selected for when immediate benefits are greater than long-term benefits (e.g., smiling when one's child presents them with a homemade drawing), when long-term benefits are greater, individuals may instead want to feel a helpful emotion, or one that will help them meet long-term goals (e.g., expressing anger when said drawing has been scrawled in permanent marker on the living room wall).

Applying this framework to disgust, it seems possible that individuals may encourage their emotions of disgust when evaluating particular moral acts or

individuals in order to effectively communicate disapproval and rejection of immoral behaviors (Hutcherson and Gross 2011). Gaining a better understanding of when individuals feel disgust within moral contexts and how this response relates to the individual's long- and short-term goals may help us understand the role that individual differences in the tendency to experience certain emotions (such as disgust sensitivity) play in forming moral judgments. For example, individuals may up-regulate their disgust within moral contexts (e.g., when a vegetarian intensifies their disgust in order to fuel their moral indignation about animal cruelty) or down-regulate (e.g., when a liberal reappraises two men kissing as an act of love) based on the current context of the judgment, and on their specific moral beliefs and goals.

The fact that two individuals who experience strong disgust arrive at different moral judgments makes more sense when taking into account the ability to regulate emotional responses, rather than assuming a static, linear relationship between emotion and judgment. This may be true of other emotional reactions as well: Individuals may up-regulate their anger when they are making judgments about punishment or assigning moral blame. It seems likely that one of the contributing factors to moral judgment is the ability to up- and down-regulate emotion, depending on the context of the moral situation and the cognitive and motivational resources that are available to the individual at the time of moral judgment – something that simple dual-process theories do not accommodate well. Yet the growing body of research looking at emotional regulation – which we believe should play a larger role in our psychological theories of morality – suggests that emotion and cognition are best viewed as a set of processes that are so deeply intertwined that it cannot be captured within a simple dichotomy. Individuals, using a variety of strategies, are able to selectively dampen or heighten emotional experiences – often in the service of their higher-order goals – and thus shape the contribution of their emotions to their moral judgments. In the same way that Jekyll cannot divorce himself from Hyde, human beings cannot divorce the cognitive from the affective. It appears that they are, quite literally, formed of the same stuffs.

The Neurobiology of Moral Cognition: Relation to Theory of Mind, Empathy, and Mind-Wandering

Abstract

A sense of morality forms the fabric of human societies. There is an ongoing debate whether the cognitive and emotional sources of moral decisions might be closely related to theory of mind, an abstract–cognitive capacity, and empathy, an automatic–affective capacity. That is, moral decisions are believed to imply representation of other individuals' thoughts and emotional states, respectively. Moreover, it has been noticed that neural activation patterns during moral cognition are very similar to the brain areas engaged during mind-wandering, i.e., neural correlates of an endogenously controlled state in the absence of a specific mental task.

Investigation of the neural substrates underlying moral cognition was greatly facilitated by the advent of neuroimaging techniques. This growing number of observation on brain activation patterns during the aforementioned tasks now

provides rich substrates for a quantitative integration of the current literature. Such large-scale integration, identifying brain areas consistently engaged by moral, social, empathic, and unconstrained cognition, then provides a quantitative basis for the comparison of their neuronal implementation. This chapter thus quantitatively assesses and reviews the neurobiological relationship between the moral network and the neural networks subserving theory of mind, empathy, and unconstrained cognition.

In conclusion, the neural network subserving moral decisions probably reflects functional integration of distributed heterogeneous networks, is dissociable into cognitive and affective components, as well as highly similar to the brain's default activity pattern.

Introduction

Moral behavior has classically been thought to be based on rational (i.e., rather conscious, controlled, and effortful) thinking. Rational explanations assumed that moral behavior arises from a conscious weighing of different rules, norms, and situational factors. In contrast, the role of emotion and intuition in moral thinking (thought to represent an unconscious, automatic, and effortless way) has been less often emphasized (Haidt 2001). Emotional explanations emphasized the influence of intuitive, subconscious emotional states that are rapidly evoked by a given situation. Taken together, *abstract–inferential* and *automatic–emotional* processing have been implicated and contrasted in philosophical, psychological, and biological accounts of moral behavior.

The association of psychological categories, such as decision-making or emotional influences thereon, with brain activity in the underlying neural networks has been greatly promoted by the development of functional neuroimaging. Positron emission tomography (PET) and the noninvasive functional magnetic resonance imaging (fMRI) allow the in vivo investigation of functional specialization in the human brain. Based on local changes in cerebral blood flow and glucose or oxygen metabolism, these techniques allow inference on regional increases in neural activation during the performance of specific tasks. Often, the neural correlates of a given task (reflecting a mental process of interest, e.g., moral decision-making) are isolated by subtraction of the activation measured during a closely related task (a control task, such as semantic or abstract decisions) that is supposed to carry the same confounds (e.g., reading) but not to evoke the mental process of interest. Over the last two decades, functional neuroimaging has then provided a wealth of information on the cerebral localization of various psychological tasks, including moral decision-making.

Notions of rationality and emotionality also serve as explanations in contemporary imaging research on the neural correlates underlying moral decisions (moral cognition). Joshua Greene (in the USA) and Jorge Moll (in Brazil) can probably be considered the protagonists in the ensuing debate. Results from fMRI studies by Greene and colleagues (Greene et al. 2001; 2004) were consistently interpreted as revealing a neuroanatomical dissociation between emotional responses and

subsequent explicit cognitive modulations in moral cognition. However, fMRI findings by Moll and colleagues (Moll et al. 2005a, 2006; Moll and Schulkin 2009) were interpreted as revealing various different psychological processes without any specific neural correlates, including group-oriented (i.e., pro-social) and self-oriented (i.e., egoistic) affective drives, in moral cognition.

It is important to note that the rational and emotional facets of moral cognition are, by theoretical arguments and empirical research, closely related to two other aspects of social interaction: theory of mind (ToM) and empathy. ToM refers to the ability to contemplate other's thoughts, desires, intentions, and behavioral dispositions by *abstract inference* (Frith and Frith 2003; Premack and Woodruff 1978). Evidently, moral decisions are influenced by whether or not an agent's action is perceived as intentional or accidental, which crucially relies on mental state inference, i.e., ToM. Consistently, behavioral data from subjects with high-functioning autism, known for impoverished ToM abilities, suggested an involvement of ToM in moral judgments, given that these individuals relied less on the agent's intentions and more on action outcomes (Moran et al. 2011). Empathy, on the other hand, refers to *intuitively* adopting somebody's *emotional state* while maintaining the self–other distinction (Decety and Jackson 2004; Singer and Lamm 2009). More specifically, empathy can be subdivided into (partially intertwined) emotional and cognitive components (Shamay-Tsoory et al. 2009). Phylogenetically and ontogenetically earlier "emotional empathy" is closely related to emotion contagion and simulation systems, while later developing, more advanced "cognitive empathy" is more related to perspective-taking and imagination systems. In particular, empathy is different from and tends to precede sympathy, which does not necessarily result in identical affect in the observer, but for instance in pity or compassionate love. In moral decisions, experiencing empathy was shown to alleviate harmful actions towards others (Eisenberger 2000). Conversely, deficient empathy skills are a clinical hallmark of psychopathic subjects and are believed to contribute to their morally inappropriate behavior (Hare 2003). Taken together, the aforementioned debate on the contribution of cognitive and emotional factors to moral decision-making may be reframed as the question whether the neural correlates of moral decisions are closer related to those of ToM or empathy – or whether there is a distinct moral module serving moral cognition.

The Neural Architecture of Moral Cognition

In the present analysis we tried to avoid the pitfalls of descriptive verbal summaries of neuroimaging results, which are inevitably subjective and hence potentially biased. Such critical verbal analyses tend to focus on a limited number of preselected aspects and tend to be biased by the authors' own adherence to a specific research area. In contrast to classical review articles, coordinate-based meta-analysis (CBMA) is hypothesis-free, data-driven, and, hence, objective by algorithmically weighing all results equally. As the CBMA method is not skewed by subjectivity, it precludes overinterpretation of expected, easily interpretable

findings and neglect of unexpected, barely reconcilable findings in neuroimaging research. CBMA might therefore help to point out consistent, yet frequently ignored findings (Eickhoff and Bzdok 2012).

Rather than a critical verbal discussion, we therefore recently performed a quantitative CBMA of the neuroscientific literature on moral cognition using the activation likelihood estimation (ALE) algorithm (Eickhoff et al. 2009). This approach represents a powerful approach to gain a synoptic and, in particular, unbiased view of distributed neuroimaging findings. In this context, ALE addresses the following key question: Where in the brain is the convergence of the included experiments' activation foci higher than expected by chance? ALE thus offers a unique opportunity to quantitatively measure concordance between neuroimaging results without the implicit assumptions of neuroanatomical terminologies, which are at times inconsistently employed. It also allows relating different neural processes to each other by performing meta-analyses on different neuropsychological phenomena. This integration and synthesis of neuroimaging data thus permits statistically defensible inference on the neural basis of psychological processes across a large number of experimental implementations and subjects samples.

The presented summary of neuroimaging studies on moral cognition included all those experiments that required participants to make (covert or overt) appropriateness judgments on actions of one individual towards others. In these studies, participants evaluated mainly textual, sometimes pictorial social scenarios with moral violations or dilemmas. While this approach has by far dominated the neuroscientific investigation of moral decisions, it should be noted, however, that it largely equates to assessing the neural correlates of identifying and judging moral violations. In contrast, they are less focused on "rightful action," i.e., the implementation of moral thoughts and knowledge in one's own behavior. Nevertheless, the analysis presented in Fig. 9.1 represents the current state of neuroimaging evidence for moral cognition. The obtained pattern of converged brain activation is in very good agreement with descriptive reviews of fMRI studies on moral cognition (J. Greene and Haidt 2002; Moll et al. 2005b). In the following, we will discuss the presumed functional implications of the individual brain areas that resulted as significant loci of convergence.

The *medial prefrontal cortex* (mPFC) is a highly associative brain region implicated in a range of complex tasks, such as action monitoring, free thought, autobiographical memory recall, and the perception of others. In fact, consistent activity in the mPFC during moral cognition was found all along its dorsoventral axis (simply put: from the upper to the lower parts of the middle front side of the brain), including the dorsomedial prefrontal cortex (dmPFC), frontopolar cortex (FP), and ventromedial PFC (vmPFC). From a conceptual perspective, the more dorsal versus more ventral parts of the mPFC are discussed to relate to cognitive versus affective processes, controlled versus automatic processes, explicit versus implicit social cognition, goal versus outcome pathways, as well as other-focus versus self-focus. Direct evidence for such fundamental distinction is however still limited. It is noteworthy that mPFC damage early in life can leave intellectual abilities intact while leading to hindered acquisition of social conventions and

moral rules (Anderson et al. 1999). Early lesioned patients (much more than adult-onset prefrontal patients) display immoral behaviors, such as stealing, physical violence, and absence of remorse in the context of impaired moral reasoning (Moll et al. 2003). In short, a child's moral development can be disrupted by early mPFC damage.

The dmPFC has axonal connections with the temporo-parietal junction (TPJ; especially connected to superior frontal gyrus) and the precuneus (especially connected BA8/9), which have both likewise been implicated in the meta-analysis of moral cognition. The *temporo-parietal junction* is a supramodal association area whose heterogeneous functional profile seems to range from attentional reallocation, filtering irrelevant stimuli, and prediction generation over processing embodied self and predicting others' action intentions to agency. Paralleling its functional diversity, the TPJ literature offers various neuroanatomical labels for this area, including the terms angular gyrus, inferior parietal lobule, posterior superior temporal sulcus, supramarginal gyrus, BA 39, PGa/PGp, as well as "pli courbe." Consequently, interpretation of the inconsistently named TPJ can be challenging

given increased metabolic activity across disparate psychological tasks, stimulus domains, and experimental modalities.

The *precuneus* is another highly integrative area, which is believed to generate internally directed thoughts in form of self-referential visuospatial imagery (Cavanna and Trimble 2006). Consistently, the precuneus appears to mediate covert reallocation of spatial attention, that is, spatial cognition in the absence of physical (e.g., eye) movements (Gitelman et al. 1999), which led to its informal nickname "mind's eye." This proposed domain-spanning role might potentially explain its various domain-specific functional involvements, such as in visual rotation, deductive reasoning, autobiographical memory retrieval, and mental navigation in space.

The *posterior cingulate cortex* (PCC) is adjacent to but distinct from the precuneus by its connections to the limbic system and thus close relation to emotion processing (Margulies et al. 2009). This area is most frequently proposed to be important for the modality-independent retrieval of autobiographical memories and their integration with current emotional states (Maddock 1999).

As another affect-related brain region, the *amygdala* (AM) is believed to automatically extract biological significance from the environment and to shape appropriate behavioral responses (Bzdok et al. 2012; Sander et al. 2003). This functional concept covers its involvement in classical conditioning, emotion regulation, social cognition, reward processing, and memory formation (Adolphs 2010; Bzdok et al. 2012; LeDoux 2000). Considering that the amygdala is probably the brain area most unequivocally linked to emotion processing and given its heightened activity across the meta-analyzed neuroimaging studies, the reverse inference on an involvement of emotional brain systems in moral cognition seems justified.

Finally, the *temporal pole* (TP; here liberally referring to the entire anterior temporal lobe/BA38) was repeatedly proposed to store verbal and nonverbal semantic knowledge, in particular, context-independent social semantic knowledge, including values and concepts of social events (cf. Olson et al. 2007; Ross and Olson 2010; Zahn et al. 2007). Examples of such conceptual social knowledge would be the meaning and ramifications of "deceitfulness" or how people dress appropriately according to given situations. In line with this, neurological lesion of the TP entails social semantic deficits, such as failing to name human actions or to recognize the name, voice, handwriting, odors, or face of familiar people. Moreover, they may result in behavioral and personality disturbances, ranging from compulsively eating flower decorations on tables to general apathy to other's distress (cf. Gorno-Tempini et al. 2004).

It can be concluded that moral cognition is neurally implemented by brain areas that tend to be highly interconnected, not specific for any single psychological task, and not dependent on a specific sensory modality but rather multimodal and "associative." Those brain areas are moreover implicated in complex psychological processes, including social cognition, autobiographical memory retrieval, mental imagery, and reallocation of attention to internal information, all of which might contribute to the final "psychological outcome," i.e., moral judgment.

Two brain areas that have also been repeatedly discussed to subserve moral cognition, however, were not revealed by the meta-analysis. First, the posterior

superior temporal sulcus (pSTS) is involved in audiovisual integration and processing biologically significant movement (Hein and Knight 2008) and was reported to increase neural activity during moral cognition in several papers. The lack of convergence in the pSTS may readily be explained by inconsistent neuroanatomical labeling. As a rule of thumb, activation in the surroundings of this cortical area was often interpreted as "pSTS" in the morality literature and as "TPJ" in the ToM literature. The convergent activation in the meta-analysis on moral cognition is, however, neuroanatomically corresponding to the TPJ. That is, observed recruitment of the TPJ during moral tasks was perhaps recurrently mislabeled as pSTS, which might have confused discussion of the TPJ and pSTS in previous neuroimaging studies on moral cognition.

Second, the delineated "moral network" did not include the dorsolateral prefrontal cortex (dlPFC), conventionally interpreted as important for attention shifting and decision-making, although brain activity in this area was discussed in several original papers and reviews in moral neuroscience. The dlPFC was specifically proposed to reflect the engagement of abstract reasoning processes and cognitive control in moral cognition (Greene et al. 2004). Heightened dlPFC activity was thus argued to promote utilitarian responses by overriding prepotent socio-emotional behavioral tendencies. The absence of *consistent* metabolic increase in the dlPFC during moral decisions might be parsimoniously explained by selective recruitment. That is, this brain region might be recruited by the "core" moral network as an auxiliary functional module depending on the specific cognitive set imposed by specific moral decisions. Rather than being part of the "core" network, the dlPFC might have been observed to increase activity in difficult personal moral judgments and approving personal moral violations because of those decisions' increased cognitive demand. The same principle of context-dependent recruitment of supplementary areas might hold true for other brain regions that were associated with moral cognition repeatedly but not consistently, including but not restricted to the anterior insula, anterior cingulate cortex, and lateral orbitofrontal cortex. Also for these regions, inconsistent neuroanatomical labeling cannot be excluded as a confounding factor in the previous literature on moral cognition.

The Neurobiological Relationship Between Moral Cognition and Theory of Mind

Performing another meta-analysis on brain activity evoked by theory of mind then allowed elucidating the correspondence of the neural substrates consistently engaged by this task and moral cognition, two psychologically related mental processes (cf. introduction). We included those neuroimaging studies into the meta-analysis of theory of mind that required participants to adopt an intentional stance towards others, that is, predict their thoughts, intentions, and future actions. These studies mostly presented cartoons and short narratives that necessitated understanding the beliefs of the acting characters. The results of the meta-analysis

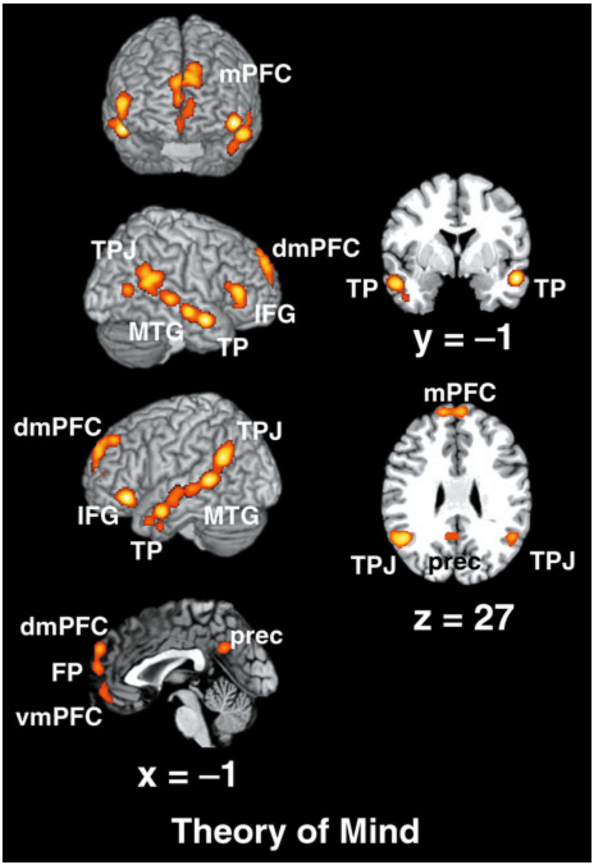

Fig. 9.2 Meta-analysis results on theory of mind. Whole-brain renderings as well as sagittal, coronal, and axial slices depicting the significant results of the ALE meta-analyses of eligible neuroimaging experiments (published until 2010) related to theory of mind (68 neuroimaging experiments). Coordinates in MNI space. All results were significant at a cluster-forming threshold of $p < .05$. *dmPFC* dorsomedial prefrontal cortex, *FP* frontal pole, *IFG* inferior frontal gyrus, *MTG* middle temporal gyrus, *mPFC* medial prefrontal cortex, *prec* precuneus, *TP* temporal pole, *TPJ* temporo-parietal junction, *vmPFC* ventromedial prefrontal cortex (cf. Bzdok et al. 2012)

of ToM (Fig. 9.2) are consistent with earlier meta-analysis of such neuroimaging studies (Spreng et al. 2009). Conceptually, the convergence across studies on ToM resulted in an *abstract–inferential social–cognitive network* implicated in the recognition and processing of others' *mental states*.

Brain activity patterns during moral cognition and ToM overlapped in the bilateral vmPFC, FP, dmPFC, and TPJ, as well as the right TP (Fig. 9.3). This extensive convergence indicates that moral cognition and ToM engage a highly similar neural network. The homologous neural implementation, in turn, entices to speculate about a close relationship between these two psychological processes and the experimental tasks to probe these. The interest in the neurobiological relationships between moral cognition and ToM recently gained momentum, which entailed publication of a small number of targeted neuroimaging studies.

A seminal fMRI study investigated the interaction of a protagonist's initial intention and subsequent action outcome by explicit moral judgments of short written stories (Young et al. 2007). The bilateral TPJ, dmPFC, and precuneus

Fig. 9.3 Relationship between the moral network and the neural network underlying theory of mind. Overlapping activation patterns between the meta-analysis on moral cognition and the difference analysis between ToM and empathy. Coordinates in MNI space (cf. Bzdok et al. 2012)

showed significant signal effects for the interaction of negative versus neutral beliefs versus outcomes. The right TPJ showed the biggest signal increase in attempted (intention) but failed (outcome) harm, that is, when nothing bad actually happened despite what the protagonist planned. Given that moral cognition and mental state attribution were probably part of the participants' cognitive set in all experimental conditions, right TPJ activity appeared to reflect special emphasis on the agent's thoughts when weighing various contextual features against each other. Consistently, transient disruption of right TPJ activity using repetitive transcranial magnetic stimulation was found not to impair moral judgments per se (Young et al. 2010). Rather, this manipulation reduced the influence of the protagonist's belief without completely eliminating it as an input to judgment formation. It is important to note, however, that further evidence from neuroimaging (Mitchell 2008) and lesion (Apperly et al. 2007) studies questioned the *specificity* of the TPJ for belief processing. Nevertheless, right RTPJ activity appears to be, comparing to other relevant areas, particularly related to processing mind states in explicit moral cognition.

The ensuing notion that the TPJ may represent a crucial link between moral cognition and ToM was confirmed by another fMRI study that set out to detail encoding and integration of intentions in the context of moral judgments (Young and Saxe 2008). While "encoding" consists in merely creating a representation of the protagonist's belief, "integration" then consists in flexibly weighing the moral judgment depending on the interaction of intention and outcome. The bilateral TPJ and precuneus were related to both encoding the protagonist's belief and integrating it with other relevant contextual features. In fact, brain activity in these regions did not differ according to belief content, in particular, its valence (negative vs. neutral). In contrast, the dmPFC was related to processing belief valence during the integration phase. The authors thus proposed that the TPJ and precuneus mainly process beliefs, while the dmPFC mainly processes morally relevant aspects of the presented stories in constructing a coherent moral judgment. Analogous to the TPJ, it is important to note that dmPFC activity might not be *specific* to belief processing as it was for instance also linked to language coherence (Ferstl and von Cramon 2002). In addition to belief, outcome, and valence, metabolic responses in the dmPFC and bilateral TPJ during moral judgments were observed to vary according to the previously experienced fairness of the judged agent (Kliemann et al. 2008). This suggests that the dmPFC and bilateral TPJ might also integrate available memory of an agent's personality traits in explicit moral judgments. Another fMRI study showed selective metabolic increase in the dmPFC, right TPJ, and precuneus in response to morally relevant facts in short stories without explicit mental state information or an explicit necessity for moral judgments (Young and Saxe 2009). This finding can be taken to argue that brain regions typically related to ToM might be implicated not only in *explicit or controlled* but also *implicit or automatic* moral cognition.

In line with the meta-analytic overlap, the reviewed fMRI studies suggest that moral cognition might involve reconstructing personality attributes and intentions

of agents as well as their integration with action outcomes and other relevant contextual features when reasoning about morally significant social scenarios. It should, however, not be underestimated that experimental similarities (i.e., employed stimuli and paradigm) between studies on moral cognition and ToM might have contributed to the observed neural homology. In other words, the congruency may appear larger than it actually is due to shared low-level features (textual descriptions, cartoon, requirement to make a judgment).

The Neurobiological Relationship Between Moral Cognition and Empathy

In contrast to ToM, the correspondence between moral cognition and empathy has hardly been investigated in targeted neuroimaging research despite their relatedness on psychological grounds (cf. introduction). The correspondence between the neural substrates reported in those largely separate lines of research was therefore juxtaposed by individual meta-analysis on either topic (Figs. 9.1 and 9.4). We included those neuroimaging studies into the meta-analysis of empathy that aimed at eliciting the conscious and isomorphic (i.e., happiness in other induces happiness in oneself) experience of somebody else's affective state. Put differently, in these studies participants were supposed to "feel into" and thus know what another person was *feeling* (rather than *thinking*, which would be related to ToM). These studies employed mostly visual, sometimes textual, or auditory stimuli that conveyed affect-laden social situations which participants watched passively or evaluated on various dimensions. Conceptually, the convergence across studies on empathy resulted in an *automatic–emotional social–cognitive network* implicated in vicariously mapping others' *affective states*.

Please note that a meta-analytic distinction between emotional and cognitive empathy cannot and should not be done at this point. It cannot be done because there are currently not enough available neuroimaging studies on cognitive empathy. It should not be done because assuming a clear-cut neurobiological dissociation between emotional and cognitive empathy would constitute a fairly strong a priori hypothesis about how psychological constructs map on brain organization.

Brain activity related to both moral cognition and empathy converged significantly in an area of the dmPFC (Fig. 9.5). An fMRI study identified a similar area as highly selective for processing guilt (Wagner et al. 2011), an emotion closely related to moral and social norm violation. More specifically, guilt was proposed to promote interpersonal relationships by immediately providing actual or anticipated emotional feedback for the acceptability of actions (Tangney et al. 2007). Moreover, the dmPFC has consistently been related to the (possibly interwoven) reflection of own and simulation of others' mind states (Bzdok et al. 2013). One might therefore cautiously conclude that convergence in this highly associative cortical area might reflect complex representational social–emotional processing. Additionally, the individual meta-analyses revealed the left AM in moral cognition

and the right AM in empathy, that is, the same area in contralateral hemispheres. A role of the AM in moral cognition is supported by correlation between its neural activity and the participants' level of self-reported emotional arousal when presented with visual stimuli of people being harmed (Decety et al. 2012). More specifically, it is known that AM activity typically increases in the left hemisphere in controlled, elaborate social-cognitive processes and in the right hemisphere in automatic, basic emotional processes (Markowitsch 1998; Phelps et al. 2001). This lateralization pattern potentially explains the consistent engagement of the left AM in moral cognition (more controlled/elaborate) and right AM in empathy (more automatic/basic). Furthermore, activity in the PCC was found in adjacent, yet nonoverlapping, locations during moral cognition and empathy. Neural activity in this brain area was observed in hearing and recalling affective autobiographical episodes, dealing with coherent social scenarios, viewing familiar faces, as well as emotional planning. The PCC was thus repeatedly proposed to integrate retrieval of past experiences and ongoing emotion processing, which is potentially shared by moral cognition and empathy.

To sum up the meta-analytic evidence, some aspects of affective processing are probably shared by moral cognition and empathy, as the respective meta-analyses

revealed convergence in the dmPFC (direct overlap), AM (oppositely lateralized), and PCC (closely adjacent clusters). A single direct overlap in the dmPFC might further suggest representational socio-emotional processing to be common to moral cognition and empathy. More generally, it is interesting to note that the neural correlates of moral cognition are more closely related to the neural signature of ToM than to that of empathy. It is an important question whether this is an epiphenomenon of methodological idiosyncracies or illustrates brain network dynamics in everyday life.

The Neurobiological Relationship Between Moral Cognition and Mind-Wandering

It is becoming increasingly clear that brain areas pertaining to social cognition are topographically highly similar to brain areas that increase activity in the idling, unconstrained mind, the so-called "default mode," and decrease activity during stimulus-driven, goal-directed tasks (Shulman et al. 1997; Spreng et al. 2009). More specifically, brain areas underlying unconstrained cognition were consistently associated with a number of complex, introspective mental tasks, including contemplating mind states, self-focused reflection, mental navigation of the body in space, autobiographical memory recall, and, more generally, envisioning situations detached from reality. Performing separate meta-analyses on moral and unconstrained cognition hence allowed elucidating the correspondence between the neural substrates consistently engaged by these two mental states. We included those neuroimaging experiments from the BrainMap database (Laird et al. 2011) into the meta-analysis of unconstrained cognition whose metadata indicated them to provide coordinates of brain deactivation (Fig. 9.6). Brain activity patterns during moral reasoning and unconstrained cognition overlapped in the vmPFC, dmPFC, precuneus, and bilateral TPJ (Fig. 9.7). Consequently, those brain areas consistently implicated in moral cognition indeed lower their activity during stimulus-driven, goal-directed cognition. More broadly, the observed similarities of the neural networks underlying moral and unconstrained cognition favor a possible relationship between the physiological baseline of the human brain and a psychological baseline implicated in constant social cognition.

What is the common denominator of moral and unconstrained cognition? It was speculated that the human brain might have evolved to, by default, predict environmental events using mental imagery. In particular, autobiographical memory supplies building blocks of social semantic knowledge. Isolated conceptual scripts may then be reassembled to enable forecasting future events (Tulving 1983). Constructing detached probabilistic social scenes could thus influence perception and behavior by estimating saliency and action outcomes (Boyer 2008; Schilbach et al. 2008). Ultimately, the tonically active default mode network might be adapted to gathering sensory information for the probabilistic mapping of the external world in order to optimize the organism's behavioral response. That is,

Whole-brain renderings as well as sagittal, coronal, and axial slices depicting the significant results of the ALE meta-analyses of eligible neuroimaging experiments (published until 2010) related to mind-wandering (533 neuroimaging experiments), i.e., brain activity in the absence of a specific task. Coordinates in MNI space. All results were significant at a cluster-forming threshold of $p < .05$. *dmPFC* dorsomedial prefrontal cortex, *HC* hippocampus, *FP* frontal pole, *MFG* middle frontal gyrus, *mPFC* medial prefrontal cortex, *prec* precuneus, *SMG* supramarginal gyrus, *TPJ* temporo-parietal junction, *vmPFC* ventromedial prefrontal cortex (Schilbach et al. 2012)

pondering over morally relevant social situations and simply letting the mind float might both imply contemplation of hypothetical social scenes that guide actual behavior.

Conclusion and Future Directions

The conjunction of the above quantitative and qualitative reviews suggests that moral cognition might rely in large extent on neural systems related to social cognition. The group of social processes subserving moral cognition appears to include contemplating mind states, emotion processing, and internally directed cognitions, such as self-referential thought, mental imagery, and perhaps even prediction generation. Additionally, the neural correlates of moral cognition were dissociated into more rational and more emotional subsystems by reference to

Fig. 9.7 Relationship between the moral network and the neural network underlying mind-wandering. Overlapping activation patterns between the meta-analyses on moral cognition and mind-wandering, i.e., brain activity in the absence of a specific task. Coordinates in MNI space (cf. Bzdok et al. 2012; Schilbach et al. 2012)

a socio-cognitive framework (ToM cognition) and a socio-affective framework (empathy), respectively. The neural network underlying moral cognition might thus be considered “domain-global” as it reflects functional integration of distributed brain networks. Put differently, no part of the brain is uniquely devoted to moral cognition but this capacity is very likely deployed across several heterogeneous functional domains. This contention concurs with the observation that there is also no single brain region specific for the development of antisocial/psychopathic behavior deficient in moral cognition (Raine and Yang 2006).

Shifting from the neural level to psychological concepts, the question “what brain areas support moral judgment?” might already be ill-posed, or at least inaccurate, because moral cognition is unlikely to be a unified psychological entity. That is, distinct (sets of) cognitive components probably support distinct classes of moral judgments. Even more fundamentally, “morality” as such might actually not be localizable in the brain at all given that it constitutes a complex cultural concept, that is, a phenomenon of human cultural evolution. Considering from a phenomenological, psychological, and philosophical point of view, there might even be nothing unique to the notion of “morality” itself. What is unique to moral judgments comparing to, for example, judgments of complex social scenarios? In short, we cannot measure “morality” itself in the human brain. Instead, we can measure brain activity of individuals lying in a neuroimaging scanner while thinking about moral issues. For these reasons, it might actually be naive to search for something like a “distinct moral module” in the first place. Furthermore, moral psychology and moral neuroscience mainly concentrated on moral decision-making, rather than the very manifestation of morality – moral behavior (see Moll et al. 2006 for an exception).

From a methodological perspective, it is unclear to what extent existing neuroimaging studies on moral cognition suffer from this potentially limited ecological validity. That is, the used experimental tasks might only partially involve the neural processes that navigate real-life moral behavior. In particular, complicated dilemmas borrowed from moral philosophy were often employed as stimulus material. This is epitomized by the “trolley dilemma” that prompts a decision between either letting five people die or actively causing the death of another single person to save the life of those five people. A tendency for artificial moral scenarios, on top of the experimental constraints of neuroimaging environments, could have entailed a systematic overestimation of cognitive versus emotional processes. The observed bigger correspondence of the moral neural network with that of ToM, rather than empathy, might thus be epiphenomenal of established experimental features.

Moreover, neuroimaging results were often discussed by qualitative comparison between studies that differ in various crucial aspects, including stimulus material (text vs. pictures/movies vs. numbers in neuroeconomic games), the participants’ perspective (engaged second-person vs. observant third-person perspective), control conditions (morally relevant vs. morally irrelevant, high-level vs. low-level), or continuity (single-shot judgments vs. multi-trial paradigms). It is conceivable that the neural instantiation of moral judgments and comparisons between those are highly susceptible to such experimental differences, especially in light of the integrative character of moral cognition.

From a neuroethical perspective, it can be said that the neuroscience of moral decision-making may be able to contribute to ethics by providing descriptive results. But one must be wary of overextending the logic of neuroimaging with regard to morality. Although moral decision-making correlates with the activation of specific regions in the brain, this does not necessarily mean that moral judgment can be reduced to this activation. A central problem is thus that an attempt is made under scientific conditions to establish which brain areas are particularly active during moral cognition without it being possible to define exactly what moral cognition as such is and without the existence of an objectifiable moral theory (Gazzaniga 2007).

Some critics even raise much more fundamental objections to imaging studies of moral cognition. They pose the rhetorical question: How can I hope at all to discover "facts" which prove "values"? All moralities and all moral decisions are in fact based on values and norms, and these cannot, or at least cannot necessarily be reduced or ascribed for their part to (neurophysiological) facts but are intrinsically subjective and hence may only be accessible on phenomenological accounts. A second question is equally important: What is the consequence if I regard and acknowledge specific activities of neuronal tissue as the basis for moral evaluations and decisions? If values and norms can be described as sequences of cellular processes, does this not remove the basis for morality? (Vogelsang 2008).

Neil Levy (2007) attempted to summarize this "challenge from neuroscience to morality" in four consecutive sentences:

1. Our moral theories, as well as our first-order judgments and principles are all based, more or less directly upon our moral intuitions.
2. These theories, judgments and principles are justified only insofar as our intuitions track genuinely moral features of the world.
3. But our moral intuitions are the product of cognitive mechanisms which evolved under non-moral selection pressures and therefore cannot be taken to track moral features of the world; hence
4. Our moral theories, judgments and principles are unjustified.

It emerges from the above that the study and objectification of processes involving moral decisions and judgments poses fundamental problems. The ability to image brain activity is much greater than the ability to draw clear conclusions with regard to questions of morality from it.

Critics also object that it is not clear to them why knowledge about neuronal processes should help us at all when it comes to morality and moral decisions. They point out that human morality – beyond all modern empirical methods of access – has always been a main topic of philosophical debate and that this debate will continue to be needed in the future (Brukamp and Groß 2010; Groß 2010). Particularly when normative conclusions are to be made on the basis of these empirical findings, the problem of the "ought" fallacy arises, as a (moral) "ought" cannot simply be derived from a (neuronal) "is." This also makes it necessary to raise the question of the scientific and normative rules for dealing with scientific studies on moral cognition. What standards must be met by the scientists who carry

out and publish studies of this kind? Is it enough for them to be experts in neuroscience esp. neuroimaging or should (additional) expertise in the field of morality and (neuro)ethics be required?

Irrespective of the abovementioned questions and concerns, detailing the neurobiological nature of moral cognition is a goal worth pursuing. Importantly however, moral neuroscience should strive for an explanation of the understanding of morality which underlies it, for realistic moral scenarios and for a more rigorous across-study discussion (cf. Knutson et al. 2010). These suggestions might help to minimize the risk of investigating "in vitro moral cognition."

Psychology and the Aims of Normative Ethics

Abstract

This chapter discusses the philosophical relevance of empirical research on moral cognition. It distinguishes three central aims of normative ethical theory: understanding the nature of moral agency, identifying morally right actions, and determining the justification of moral beliefs. For each of these aims, the chapter considers and rejects arguments against employing cognitive scientific research in normative inquiry. It concludes by suggesting that, whichever of the central aims one begins from, normative ethics is improved by engaging with the science of moral cognition.

Three Central Questions of Normative Ethics

It is undeniable that the field of empirical moral psychology has grown dramatically in the last decade, with new experimental techniques allowing us unprecedented understanding of the causal and computational structures of the human moral faculty. Or, at least, it is undeniable that this research contributes to a *descriptive* project, one of better understanding the facts about who we are and how we think (Doris and Stich 2007; Appiah 2008; Levy 2009; Knobe 2010). But what might be denied is that these investigations have much to offer to normative ethics, a distinctively *prescriptive* sort of inquiry.[1] The purpose of this chapter is to show why normative ethics – the study of how we ought to live our lives and what we ought to value – can indeed benefit from engagement with empirical moral psychology.[2]

It makes sense to begin with some conception of what normative ethics *is* and how the inquiry operates. Unfortunately, there is nothing like consensus on those matters among ethicists. Therefore, this chapter pursues a piecemeal dialectical strategy, setting out different ways one might characterize the discipline, and then asking of each in turn how empirical moral psychology might be brought to bear.

Each of the following is a *central question* of normative ethics:

1. What is it to be a moral agent?
2. Which actions are morally permitted or required?
3. Which of our moral beliefs are justified?

These questions are not necessarily rivals; one could certainly hold that normative ethics aims at addressing *all* of these questions. Some philosophers do see one of these questions as conceptually prior to the others, or indeed see one as exhaustively constituting the subject matter of normative ethics, but those disputes will not be engaged here.

Each of the following sections discusses one of these questions, and each section follows a common structure. First will be a *negative* argument, one claiming that answering the target central question allows little relevance for empirical moral psychology. This followed by a reply, arguing that further reflection on the central

[1]There is one sense in which no one doubts the relevance of empirical findings to normative ethics. That is in *applying* settled normative views to actual circumstances. Obviously psychology – and ordinary daily experience – can aid us in learning how to bring about the moral goals we have set, once those goals are *already* determined. What is at issue in this chapter is something different: Can empirical moral psychology play a role in helping to determine what the moral goals themselves ought to be?

[2]Some clarification about terms: The use of “empirical moral psychology” is meant to be ecumenical, encompassing research by psychologists, neuroscientists, biologists, behavioral economists, sociologists, and experimental philosophers. “Normative ethics” refers to the branch of moral philosophy concerned with how we ought to live our lives, what things we ought to value, and what practical decisions we ought to make. This chapter does *not* discuss certain related topics, such as free will and moral responsibility, or naturalistic moral ontology.

question instead favors a more welcoming conclusion for empirical moral psychology. Finally, there are illustrative examples of relevant empirical research. The point of this structure is partly expository, since the chapter aims to provide an overview of many branches of a growing debate. But there is also a dialectical strategy here: If it can be shown that, *whichever* of the three central questions one begins from, negative arguments can be reversed into positive arguments, then the relevance of empirical moral psychology should be convincingly secured.

What Is It To Be a Moral Agent?

Challenge: Rational Agency and the Practical Perspective

Most healthy adult human beings are moral agents, capable of engaging with moral reasons and being held morally responsible for their actions. But what constitutes a moral agent? Many philosophers have thought that answering this question is central to normative ethics, in that providing an answer would subsequently guide theory about how to live our lives. This section begins by sketching one very influential answer – one which appears to have the consequence of rendering empirical psychology irrelevant to normative ethics.

The Enlightenment philosopher Immanuel Kant claimed that basic elements of normative ethics (such as his famous categorical imperative) follow directly from a conception of moral agency as grounded in *rational nature*.[3] According to Kant, taking moral decisions seriously requires thinking of ourselves as rational beings, as beings who can determine for ourselves the rules that govern our actions, rather than being determined by the laws of nature that govern everything else. When we take up the question of how we should live our lives, it makes no sense to think of ourselves in terms of natural laws. Asking what we *should* do presupposes that we have some say in the matter, whereas an investigation of natural laws aims at showing what *must* happen. So for Kant, moral inquiry is fundamentally *practical*, in that it is conducted from an orientation aimed at guiding genuine choices, and not simply at describing the world.

Clearly, on this conception of moral agency, there will be difficulties employing empirical moral psychology in normative ethics. Psychology concerns itself with the causal structure of our thought; in Kant's terms, it aims at describing the natural laws that govern how we think. But describing causal structures *cannot be* the same project as deciding how we ought to live our lives, which takes place from the practical perspective. So Kant was highly critical of theorists who attempted to

[3]The clearest statement of Kant's view on this point comes in Book 3 of his *Groundwork for the Metaphysics of Morals* (Kant 1785). Interpreting Kant is always a delicate matter, and there is not space here to fully explicate the interpretation given in the text, which mostly follows Korsgaard (1996a).

draw moral conclusions from contingent facts about the human mind and its circumstances. Instead, he thought, we must pursue "a pure moral philosophy which is fully cleansed of everything that might be in any way empirical and belong to anthropology."[4] Many contemporary philosophers follow Kant here, arguing that psychological approaches simply confuse the practical point of moral inquiry. So, writes Thomas Nagel, "The pursuit of objective practical principles is not to be conceived of as a psychological exploration of our moral sense, but as an employment of it (Nagel 1986, pp. 150–151)". (See also Nagel 1978 and Fried 1978.)

Reply: Reflective Agency and Self-Understanding

It seems best to concede the core of Kant's criticism: There is something distinctive about conceiving of ourselves as moral agents, and this does not sit well alongside a psychological self-conception. But, unless we adopt a very radical sort of metaphysics, it seems we must still admit that, in the end, we *are* subject to the laws of nature, including psychological laws. Kant need not deny this: His point is simply that there is a problem in *simultaneously* thinking in this way and thinking of ourselves from the practical perspective.[5] The two perspectives, practical and psychological, cannot be entered into at the same time.

This is not a particularly satisfying conclusion. It makes the practical perspective look a bit like a petulant child: covering her eyes, plugging her ears, and refusing to acknowledge the presence of the laws of nature all around her. And it makes the psychological perspective sound myopic and sterile, divorced from the things we actually care about in life. The problem here comes from Kant's refusal to engage with contingent, empirical facts about human nature: He insists upon seeing a moral agent strictly as a *rational* agent, with no other attributes. Could we dispense with this aspect of Kant's approach, permitting consideration of some contingent elements of our nature, without abandoning the essential point of the practical perspective?

A very appealing approach emphasizes that we are *reflective* entities. Unlike mechanical devices or simple animals, we can think about the motives of our thoughts and actions, and it is essential to our nature that we have the ability to reflectively endorse or refrain from endorsing these motives (Frankfurt 1971). Christine Korsgaard, in developing her contemporary Kantianism, has taken

[4]Kant (1785), *Ak* 4:389. Kant is quite strident on this point; he goes on to insist that an empirical approach to fundamental moral principles gives only a "base way of thinking," "disadvantageous to the purity of moral themselves… a bastard patched together from limbs of quite diverse ancestry" (4:425–426).

[5]Kant often certainly sounds as if he *is* making a metaphysical claim, where adopting the practical perspective entails denying that the world really contains deterministic natural laws. But this is not the only interpretation available. See Korsgaard (1996a).

a leading role in highlighting the role of reflection in moral agency. Korsgaard offers what she calls the *transparency* requirement on normative ethics:

> A normative moral theory must be one that allows us to act in the full light of knowledge of what morality is and why we are susceptible to its influences, and at the same time to believe that our actions are justified and make sense.[6]

The reflective perspective, unlike Kant's practical perspective, is not incompatible with acknowledging contingent facts about our nature. It need only insist that our focus must be on *evaluating* these natural facts, rather than merely describing them. Understood this way, the reflective perspective does not at all reject the relevance of empirical psychology to normative ethics. In fact, it supports an argument *requiring* psychological inquiry:

The Self-Understanding Argument

1. Being moral *agents* requires that we understand and endorse the motives of our judgments and actions.
2. Many of the motives of our judgments and actions can only be fully understand in light of findings from empirical moral psychology.
3. Therefore, in order to be effective moral agents, we must pay attention to discoveries of empirical moral psychology.

I take it that step (1) is granted by anyone who prefers the gentler reflective perspective over Kant's mysterious practical perspective.[7] Step (2) is best shown through example.

Examples: Human Nature and Normative Ethics

If one wants evidence for how empirical psychology might aid in reflective self-understanding, it could help to look away from Kant for awhile. Another deep tradition in moral theory sees morality as a natural phenomenon, growing out of basic facts about the biological constitution of human beings and their relations to one another (Foot 2003; Kitcher 2011). Owen Flanagan (1996) traces this tradition from Aristotle through John Dewey, and argues that informing moral philosophy through contemporary psychology is another, necessary iteration. The traditional Aristotelian approach assumed that there is an ultimate *telos*, or purpose, to human nature, that the essence of being human is aiming at a state

[6](Korsgaard 1996b, p. 17). For a related discussion specifically regarding psychological findings, see Kamm (2009, p. 469).

[7]Although objections to step (1) are possible, one might challenge the idea of agency itself, or at least the idea that reflective endorsement is a necessity for it. Doris (2009) makes an argument of this sort. Alternately, one might suggest that the connection between steps (1) and (2) is less clear. See van Roojen (1999) for an argument that the kinds of reasons relevant to moral agency do not map onto the kinds of motives discussed in psychological theory.

of perfected humanness. One need not take teleology on board to adopt this sort of view. The key point is simply that understanding how we ought to live our lives begins with understanding what sorts of creatures we are, in our capacity as rational agents *and* as contingent, limited organisms. When we attend to empirical discoveries, we may find grounds for reevaluating tenets of normative theory.

Start, for instance, with biology. The primatologist Frans de Waal argues that social contract theory (the sort advocated by Hobbes and Rawls) assumes that the construction of complex social arrangements is needed to mitigate the effects of individual self-interest. However, de Waal claims, careful study of primate behavior and the evolutionary origin of the human species would instead lead to the conclusion that we are predisposed to social cooperation; we are "obligatorily gregarious" (de Waal 2006, p. 4). If this is recognized, then one of the central puzzles of moral inquiry becomes inverted: Instead of trying to explain why we ever cooperate, we should instead focus on understanding why we sometimes fail to do so. This explanatory inversion does not eliminate the need to reflectively evaluate our altruistic practices, but it does suggest that there is far less distance between our natures and our norms than many had assumed (see also Petrinovich et al. 1993 and Sripada 2005).

Now consider social interaction. Gossip is often thought of as morally extraneous: idle chatter aimed purely at titillation, rather than at seriously evaluating the ethicality of particular actions. But according to (Sabini and Silver 1982, p. 101), who argue partly on evidence from social psychology, gossip in fact fulfills an essential role in moral practice. Gossip, they say, functions to coordinate social norms, and does so in a way permitting far greater detail and nuance than what is possible in formal moral instruction or debate. If this is right, we might wish to reevaluate how we regard gossipers. And, more importantly, normative ethics might benefit from examining moral commitments disclosed through informal gossip, alongside more traditional moral intuitions.[8]

Two important and ambitious research programs provide wide-ranging treatments of our psychological moral nature. One is the developmental tradition pioneered by Jean Piaget, and extended by Lawrence Kohlberg.[9] According to this account, human moral judgment arises from an invariant sequence of developmental stages, each consisting of logical improvements upon the limitations of prior stages. Kohlberg regards this account as capturing the essence of the moral domain so completely that, he says, "an adequate psychological analysis of the structure of

[8]Similar comments apply to the phenomenon of moral *disagreement*. Knowing how and why people come to hold diverging moral views – between various communities (Moody-Adams 2002; Haidt 2012) or even within individual minds (Cushman and Young 2009) – might provide clues as to how to deal with them.

[9]Piaget, in fact, aims his work squarely at addressing Kant's challenge to empirical psychology. Piaget's developmental account is explicitly intended to reveal the nature of moral agency (or autonomy). For a development of Piaget's views on normative ethics, see Rini (unpublished manuscript).

a moral judgment, and an adequate normative analysis of the judgment will be made in similar terms."[10]

A second, more recent, research program concerns the interpretation of moral intuitions. Reflective equilibrium, the dominant method of contemporary normative ethics, involves soliciting intuitive reactions to test cases, which are systematized in search of latent principles. The method is most fully articulated in the work of John Rawls (1951, 1971), where it is primarily presented as a means of *justifying* moral principles. But Rawls himself noted a resemblance to the *descriptive* enterprise of linguistic psychology (Rawls 1971, p. 47). A number of authors (Mikhail 2011; Dwyer 2006; Hauser 2006) have pressed this *linguistic analogy*, arguing that moral intuitions result from a domain-specific, partly innate cognitive, mechanism, by which our minds map the causal structure of observed situations onto morally valenced reactions. The suggestion is that if reflective equilibrium has an aim of finding the underlying structure of our moral intuitions, then surely the powerful empirical techniques of psychology can be an aid to purely introspective theorizing.[11]

All of these examples are susceptible to empirical challenge, and certainly not everyone is persuaded by each. But the overall point should be clear: To the extent that reflective self-understanding plays a central role in normative ethics, empirical psychology enhances rather than detracts from this role. The claim is not that descriptive psychological findings lead immediately to substantive normative conclusions. Rather, the claim is that a reflective approach to normative ethics unnecessarily hobbles itself if it refuses to engage with this powerful form of self-understanding.

Which Actions Are Morally Permitted or Required?

Challenge: The Is-Ought Gap

In his *Treatise of Human Nature*, David Hume famously expressed surprise at finding other authors moving from claims about what *is* the case to claims about what *ought to be* the case. According to Hume, it "seems altogether inconceivable, how this new relation ['ought'] can be a deduction from others, which are entirely

[10](Kohlberg 1971, p. 224). For a critical appraisal of Kohlberg's normative claims, see Goodpaster (1982). Kohlberg's findings have also been criticized on empirical grounds, especially by his former collaborators (Gilligan 1982) and (Turiel 1983). For more recent work in the developmental tradition, see Rest et al. (1999) and Narvaez and Lapsley (2009).

[11]The linguistic analogy has been criticized both for its normative claims (Daniels 1980) and its empirical grounding (Dupoux and Jacob 2007; Prinz 2008). For general discussions of descriptive interpretations of reflective equilibrium, see Scanlon (2002) opposed, and Rini (2011, Chap. 3), in favor. A closely related research program, focused on describing the causal role of intention-ascription in moral judgment, provides a detailed example of what careful empirical work can uncover (Knobe 2003; Young and Saxe 2008; Cushman 2008).

different from it. (Hume 1739, Book III, sec 1, part 1)" Hume here articulated the *is-ought gap*: the doctrine that descriptive claims (about how matters actually are) constitute a logically different sort than prescriptive claims (about how matters should be), and therefore that something goes wrong when one attempts to generate prescriptive claims from purely descriptive ones.

The is-ought gap is related to a central aim of moral philosophy: identifying which *actions* ought to be pursued. For Hume, the gap stemmed from the idea that moral claims are intrinsically motivational in a way that descriptive claims are not. During the twentieth century, the is-ought gap was frequently formulated as a point about moral *language* (Moore 1903; Mackie 1977, pp. 64–73; Joyce 2006, pp. 146–156). According to a particularly influential mid-century view, moral vocabulary has an imperative logic, even when its surface grammar appears descriptive. For instance: "you have an obligation to help the needy" appears to *describe a fact* about you (your having a thing, an obligation), but it is actually logically similar to the command, "you, go help the needy." If this view is correct, then it is a misuse of language to suggest that moral claims follow from factual claims in any logical sense.[12] Imperatives do not logically follow from declaratives.

Whatever its grounding, the is-ought gap has an intuitive plausibility. The question of what we should do, of what sorts of actions we should engage in, is simply not answered by a purely descriptive characterization of our existing tendencies to engage in or avoid particular actions – and these are precisely the sorts of things studied by empirical moral psychology. There is, then, at least a prima facie burden to explain how psychological inquiry can produce any conclusions relevant to "ought" considerations.

Reply: Ought Implies Can

Alongside the is-ought gap sits another venerable philosophical dictum: "ought implies can." It does not make sense to claim that one "ought" to do something unless it is possible for the person to do so (though see Graham 2011 for a recent opposed view). For instance: It is nonsense to insist that you, personally, ought to stop a dangerous meteor from striking the Earth, because individual people simply do not have this ability. If moral theory aims at providing guidance to actual ethical decisions, then it must respect the limitations of actual human ability.

Applications of "ought" implies "can" are fairly obvious in cases of temporal or physical impossibility. The present argument aims to draw attention to less obvious cases of *psychological* impossibility. Our minds are limited in various ways, and a genuinely action-guiding normative ethics should be attentive to

[12]For examples of the linguistic formulation of the is-ought gap, see Stevenson (1944, pp. 271–276) and Hare (1952, pp. 17–55). Williams (1985, pp. 121–131) argues that the linguistic formulation does not clarify matters.

these limitations. This is the kernel of Owen Flanagan's *Principle of Minimal Psychological Realism*:

> Make sure when constructing a moral theory or projecting a moral ideal that the character, decision processing, and behavior prescribed are possible, or are perceived to be possible, for creatures like us.[13]

If we accept this Principle, then clearly empirical moral psychology will be essential to the aims of moral philosophy. Our best clues about our psychological limitations will surely come from empirical inquiry. Moral theory constructed in ignorance of these limitations will issue frustratingly unfulfillable prescriptions.

It is worth distinguishing two ways in which we could be psychologically incapable of meeting some particular moral prescription. The first way is *cognitive*: The prescription requires us to make decisions that involve resources of calculation, memory, or imagination which we do not possess. Consequentialist moral theorists have long been challenged to explain how it could be possible for actual agents to recognize, let alone calculate, the mushrooming consequences of their individual actions, to which they have developed complex responses (Sidgwick 1907; Hooker 1990). But there may be more subtle cognitive limitations on our moral thinking. For instance, Horgan and Timmons (2009) argue that the "frame problem" from cognitive science – concerning the difficulty of providing a discrete specification for the domain of any particular decision – shows that our moral psychology cannot consist solely in a set of general, exceptionless rules, and therefore any moral theory that does consist in such rules violates the "ought"/"can" stricture.[14]

The second way we may be psychologically limited concerns our *motivations*. It may be that we have strong, persistent motivations to behave or refrain from behaving in particular ways. A moral theory that requires us to do things we cannot feel motivated to do is not much use for action-guidance. Petrinovich et al. (1993) and Petrinovich and O'Neill (1996) argue that evolutionary psychology can uncover "biological universals" among human motivations, which are likely to be strict limitations, given their hard-wiring in our adaptive history. Psychological limitations can also play a role in evaluation of social practices. So, writes John Rawls: "It is... a consideration against a conception of justice that in view of the laws of moral psychology, men would not acquire a desire to act upon it even when the institutions of their society satisfied it. For in this case there would be difficulty in securing the stability of social cooperation."[15]

[15](Rawls 1971, p. 138). Rawls continued to draw attention to this role for psychological findings in his later work (Rawls 1974, p. 294, Rawls 1987, p. 24). Rawls' attention to psychological realism has brought his method criticism as overly conservative, but an ought-implies-can argument like the one sketched in this section may actually show this sort of conservatism to be a theoretical virtue. See Rini (2011, Chap. 3).

A strong objection can be raised against the argument from psychological possibility, especially in its motivational form: Often, when we claim that some act is not psychologically possible for us, we are merely using psychology to invent *excuses* for not honoring difficult or unpleasant moral duties. Without question, this is a concern that we ought to address for any particular application of this argument. But then it really will come down to the empirical details, to determine just how malleable our cognitive or motivational capacities are (Schleim and Schirmann 2011). So this point is best understood as a cautionary note rather than a direct objection to the argument.[16]

Examples: Virtue and Psychological Limitations

Interestingly, the argument from psychological possibility is illustrated on *both* opposing sides of an ongoing debate over the relationship between cognitive science and virtue ethics. Virtue ethics is a substantive normative theory, due in large measure to Aristotle, which understands morally correct actions and motivations as those possessed by a person with good moral character. Virtues are stable dispositions of character, inclining one to engage in appropriate actions across a range of circumstances. Virtue ethics has experienced a recent revival, especially in the views of those who see it as providing a richer conception of moral life than offered by other theories (Anscombe 1958; MacIntyre 1981; Hursthouse 2002).

One research program claims that central findings from cognitive science "are more consilient with the assumptions of virtue theory than with other theories (Casebeer and Churchland 2003, p. 173)" (See also Clark 1996 and Churchland 2011). While this position is partly supported by positive arguments – from affective neuroscience and the predictions of connectionist neural modeling – one of its central premises is an ought-implies-can argument against rival theories. According to Paul Churchland, consequentialist and deontological normative theories "surreptitiously presuppose a background theory about the nature of cognition, a theory that we now have overwhelming reason to believe is empirically false."[17] The idea is that cognition in general, and so moral cognition in particular, cannot be partitioned into discrete belief-states with unique logical conditions. Since living according to other normative theories *would* require that sort of psychology (at least according to proponents of the argument), those theories are disqualified on ought-implies-can grounds. Virtue ethics, by contrast, is held to be the only normative theory compatible with the purported facts about cognition.

[16]Even Peter Singer, usually quite uncompromising about the demandingness of morality, allows moral theory to bend for certain psychological limitations. For instance, Singer notes that partiality toward family runs contrary to impersonal consequentialist theory. However, he says, familial partiality is so biologically entrenched that it is better to harness it – and so secure reliable concern for local welfare – than to attempt to fight it. See Singer (1981, pp. 33–36).

[17](Churchland 2000, p. 294). This negative argument is related, but not identical, to Horgan and Timmons' (2009) frame problem, discussed above. For further related arguments, see Stich (1993) and Johnson (1996).

A quite different research program suggests the opposite: Evidence from cognitive science *undermines* the tenability of virtue ethics as a normative theory. Robust findings in social psychology, drawn together under the heading of Situationism, suggest that most human behavior is explained not by persistent character traits, but by automatic responses to narrow situational factors (Darley and Batson 1973; Milgram 1973; Haney et al. 1973; Ross and Nisbett 1991). If this is so, then people simply do not have general character traits – such as courage or fidelity – in the way virtue ethics requires (Doris 2002; Harman 1999; for criticism see Kamtekar 2004; Annas 2005; Sabini and Silver 2005). If it is not possible for people to possess the relevant sort of character traits, then a normative theory evaluating them on that basis cannot be of much use.

Debate over the status of virtue ethics continues, with contributions from psychologists and philosophers alike. However, these arguments ultimately resolve, it is instructive to note the implied agreement among their participants, that moral theory must be responsive to the limitations on human agency revealed by psychological inquiry.

Which of Our Moral Beliefs Are Justified?

Challenge: Justification and Explanation

A final central aim of normative ethics is epistemic: We aim to determine which of our moral beliefs (about actions or states of affairs) are *justified*. We presume that some of our existing moral beliefs are *not* justified; we aim to sort out which of these are, and to eliminate them from our normative theories. One way we do this, in reflective equilibrium, involves reflective consideration of moral intuitions solicited by relevant test cases. Those beliefs which best unify intuitions surviving reflective scrutiny are the ones we take to be justified. The others get discarded, and a complete moral theory is constructed only from justified beliefs.

In contrast, a project of simply *describing* our present beliefs cannot be responsive to the question, as it would not discriminate between justified and unjustified beliefs. So it is unclear how empirical moral psychology could have any relevance here, since it is just such a descriptive enterprise. More particularly, empirical psychology aims at *explaining* the causal structure of our beliefs. But, as many philosophers have noted, explaining a belief and justifying a belief are logically separate pursuits. From a first-person perspective, that of the person who "owns" the moral belief, an explanation of its causal structure has no obvious bearing on the matter of whether one ought to go one believing it. Writing in this vein, Ronald Dworkin asks us to imagine that new discoveries show some of our beliefs about justice to be secretly motivated by concerns of self-interest:

> It will be said that it is unreasonable for you still to think that justice requires anything, one way or the other. But why is that unreasonable? Your opinion is one about justice, not about

> your own psychological processes... You lack a normative connection between the bleak psychology and any conclusion about justice, or any other conclusion about how you should vote or act. (Dworkin 1996, pp. 124–125)

As Dworkin's example suggests, psychological findings cannot themselves tell us which of our moral beliefs are justified, because such findings are not *about* the content of moral beliefs. An explanatory inquiry has a different subject matter than a justificatory inquiry (see Strawson 1974, p. 25; Nagel 1997, p. 105).

Reply: The Conditions of Moral Judgment

Immediately following the quotation above, Dworkin concedes that the "bleak psychology" might lead you to rethink your moral beliefs, *if* you added a normative premise stepping from the factual claim to a normative conclusion. For instance, you might decide that aims pursued from covert self-interest are morally unacceptable. Indeed, once such normative premises are included, explanations for beliefs are readily conceded to undermine apparent justifications; philosophers have a notion of "explaining away" intuitively grounded beliefs for precisely this purpose.

In fact, established methodology in normative ethics allows that moral intuitions can sometimes be disqualified on grounds of their *originating conditions*. We sometimes reject an intuition not because of its content (i.e., that some action is right or wrong), but because the thinking that led to the intuition occurred in some concrete situation which we regard as unlikely to generate credible intuitions. So, for instance, we do not trust intuitions originating when we are distracted, tired, intoxicated, etc. Self-interest, indeed, may be another such condition: We think we do well not to trust moral intuitions formed while we are primed to worry about our own stake in some matter.[18]

Notice that the practice of excluding intuitions on grounds of originating conditions does not challenge Dworkin's claim. In these cases, we must still have a normative premise – perhaps implicit – that intuitions formed under conditions of intoxication or self-interest are *unreliable* intuitions, intuitions that cannot convey justification to any belief or theory constructed from them.[19] Excluding intuitions requires stepping beyond an explanatory project and into a justificatory one.

It may be best for proponents of empirical moral psychology to concede all of this, because it shows their program to be simply an extension of existing philosophical methodology. Since it is already accepted that originating conditions are sometimes grounds for disqualifying intuitions, there should be no principled

[18]Rawls stresses that his method of reflective equilibrium is meant to operate only upon "considered moral judgments," which are a class of intuitions rendered according to constraints like these. See Rawls (1951, p. 179) and Rawls (1971, pp. 47–48).

[19]There is a difficult issue here about what *type* of norm plays this role: Intoxicated intuitions might be excluded on epistemic grounds (intoxication being though not conducive to truth in *any* domain), while the self-interest exclusion may represent a distinctively *moral* norm. But such issues can be set aside here.

objection to similar arguments employing psychological premises – provided these arguments also include satisfactory normative premises.

What psychology uniquely offers is an enhanced understanding of the nature of originating conditions. Sometimes it is easy to notice that certain particular intuitions have occurred under conditions of intoxication or self-interest; we can know this through direct self-observation. But other times, facts about the conditions in which our intuitions originate are less obvious to us, such as when we do not realize we are primed for self-interest, or even when we do not recognize the intoxicating influence of some drug or environmental cue. The observational and correlational powers of empirical psychology are likely to be far better at tracking such originating conditions. More importantly, psychology may allow us to come to recognize *new* categories of disqualifying originating conditions, by exposing the causal relations embedded within them.

Examples: Psychological Originating Conditions

Originating condition arguments are among the most commonly used by contemporary empirically informed normative ethicists. The examples discussed in this section are intended to be illustrative of the style of argument, and this is certainly not an exhaustive survey.

For a first example: Many recent studies appear to show that our moral intuitions are highly sensitive to emotional manipulation, via environmental cues like physical cleanliness or emotional levity (Schnall et al. 2008; Valdesolo and DeSteno 2006; see also Wheatley and Haidt 2005; Eskine et al. 2011; Strohminger et al. 2011). Haidt (2001; Haidt and Bjorklund 2008) suggests that these correlations show virtually all moral thinking to be "rationalization" rather than genuine reasoning.[20] Greene (2008) makes a more selective argument, claiming that deontological intuitions in particular are shown by neuroscience to be correlated to an unreliable sort of emotional processing.[21] Both of these arguments rely on the normative premise that *emotional* influence undermines the justificatory status of a moral intuition, something one might very well dispute (see Sherman 1990; Nussbaum 2003; Nichols 2004; Narvaez 2010). For the moment, the point is only this: Haidt and Greene have used psychology to identify the influence of emotion where one might not have suspected it, so if one *does* agree that emotional influence is a disqualifying originating condition, then one ought to pay close attention.

[20]It should be noted that in Haidt's later work (Haidt 2012), he downplays the centrality of emotion and instead focuses on *automated* cognition. For critical discussion of Haidt's view, see Pizarro and Bloom (2003); Kennett and Fine (2009); Liao (2011); Huebner (2011), among others.

[21]See Greene (Greene et al. 2001, 2004) for the psychological background. For further discussion, see the references given in parenthesis (Singer 2005; Nichols and Mallon 2006; Allman and Woodward 2008; Kamm 2009; Kahane and Shackel 2010; Kumar and Campbell 2012). Berker (2009) offers a particularly comprehensive criticism of the empirical and normative aspects of Greene's argument.

Another argument of this sort works slightly differently. Rather than tying intuitions to emotion, this argument instead aims to extract the computational *rules* guiding our intuitions. The substantial literature on *moral heuristics* is central here. According to this literature, moral judgment is like judgment in other domains: Many of our intuitions result from the rapid, unconscious application of decision rules. These rules are usually reliable within their target domains, but under certain circumstances, they produce systematic errors.[22] Importantly, the conditions under which these errors arise are often extremely subtle, likely to be detected only by psychological techniques, rather than introspective self-monitoring. Of course, the claim that certain applications of the rules count as *errors* is a normative premise, not provided by psychology itself. But, again, psychology's contribution to this argument is irreplaceable; the reevaluations urged by the argument could not have occurred without empirical discoveries.[23]

All that said, it is worth drawing a cautionary line around these arguments. Their proponents often have stridently ambitious aims, attempting to undermine or displace long-established moral theories. Sometimes these revisionary ambitions appear to get the better of their authors, leading to minimization of the role of normative theory itself in their arguments. For example: Horowitz (1998, p. 381) and Greene (2008, p. 70) each spend a good deal of time demonstrating the psychological correlates of particular intuitions, then rather hastily assert that the correlated factors are "nonmoral" or "morally irrelevant," with little to no justification for these assertions. Many readers go away unconvinced. But the argument of this section does not depend on the specifics of any of these examples – they are meant simply to illustrate the form of originating conditions arguments. Certainly more work needs to be done on the normative premises of these arguments – but the logic itself seems clear.[24]

---

[22]For more on moral heuristics, see the references given in parenthesis (Baron 1994; Horowitz 1998; van Roojen 1999; Kamm 1998; Sunstein 2005; Gigerenzer 2008; Appiah 2008). Sinnott-Armstrong (2008) makes a related, and still more ambitious, argument, claiming that the influence of morally irrelevant factors like framing effects or presentational order is so pervasive as to cast an epistemic shadow over *all* moral intuitions. This sort of argument is not unique to the moral domain – see Weinberg (2007); Alexander (2012, Chap. 4) for related criticism of the role of intuition in all areas of philosophy.

[23]Many responses to the moral heuristics argument and Greene's argument, including most of those mentioned in footnotes above, involve challenging their particular empirical or normative premises. Another response, suggested by Levy (2006), claims that a constructivist meta-ethic can immunize us to many of these challenges. If one holds that morality simply *is* whatever our intuitions (or some suitably restricted class of them) correspond to, then there is little danger of our intuitions turning out driven by "morally irrelevant" factors – the psychological findings will simply tell us what our moral beliefs have been committed to all along.

[24]See Rini (forthcoming) for discussion of a broader theoretical framework for arguments of this sort. Similar moderate approaches – sympathetic to empirical investigation, but issuing cautionary qualifications – can be found in the references given in parenthesis (Stevenson 1944, p. 123; Baier 1985, p. 224; Noble 1989, p. 53; Held 1996, p. 83; Appiah 2008; Tiberius 2010; Kahane forthcoming). But see Machery (2010) for a skeptical argument, accusing the moderate approach of circularity.

Conclusion

This chapter has identified three central aims of normative ethics, shown how each aim might seem to suggest strong limitations on the relevance of empirical moral psychology, then argued that in fact, each aim actually supports an important role for psychological inquiry. Each of these discussions thus constitutes an independent argument for sustaining and expanding normative ethicists' engagement with empirical findings.

But these disciplinary interactions are at quite early stages. The arguments discussed above only hint at the rich range of questions still to be investigated. Will new psychological discoveries prove more difficult to accommodate to reflective, practical agency? If our psychology imposes limits on what morality can demand of us, should we try to change our psychology? How pervasive are undermining originating conditions – will recognizing their extent risk general moral skepticism? We do not have answers to these questions. We do not yet even know precisely how to ask these questions in a way that they might be answered. Philosophers and psychologists have a lot of work to do together.[25]

11 Moral Intuition in Philosophy and Psychology

Abstract

Ethicists often appeal to moral intuitions in defending a theory. In this practice, the contents of intuitions are taken to support moral beliefs in a way that is often compared to the way the contents of perception support empirical beliefs. Philosophers have defended a variety of positions about the nature of such states. Intuitionists believe intuitions are either self-evident beliefs or intellectual appearances, while Coherentists think of them as considered judgments that need to be balanced against each other in a process of reflective equilibrium. Intuition skeptics reject either kind of justificatory role. Such skepticism has recently received support from psychological studies of moral intuition. In contrast to philosophers, psychologists typically think of intuitions as snap

judgments that result from automatic, nonconscious, and often affective processing. Some argue that they are likely to be responsive to morally irrelevant factors. Yet even if this is true of snap judgments, it is not clear what follows for the epistemic standing of the kind of states that philosophers talk about. The aim of this chapter is to clarify the various philosophical and psychological conceptions of moral intuition in order to bring them in closer contact and help researchers in different disciplines to avoid talking past each other. In the final section, a sentimentalist account of moral intuition that may offer some hope of reconciling the philosophical and psychological approaches is quickly sketched.

Introduction

Almost everyone agrees that ethical disputes cannot be resolved by appealing to empirical evidence alone. How, then, can we settle which moral principles to adopt or what to think of a particular moral issue? It is not uncommon for philosophers to appeal to *intuitions* as fundamental evidence or source of evidence. Is this practice justifiable, particularly in the light of recent findings in psychology and neuroscience?

To begin with, we have to know what we are talking about. The term "intuition" has many related uses in philosophy and psychology. Generally speaking, intuition contrasts with reasoning and has connotations with spontaneity and insight. But closer examination reveals that there are a number of different phenomena in this area, with the result that we must take great care to avoid talking past one another. My goal in this chapter is to clarify these distinctions and relate different conceptions in different disciplines to each other, in the hope of understanding better when and why we may rely on intuitions in ethical inquiry.

The most obvious distinction is between intuition as a kind of psychological *faculty* and intuition as a psychological *state*. In the first sense, intuition contrasts with reason and vision, for example. It is something we can make use of when forming beliefs. Some Early Modern Rationalists may have believed that we have such a special capacity to gain immediate access to abstract truths. But few if any contemporary philosophers believe in any such faculty, so this sense can safely be left aside here.

The crucial questions thus concern the nature and significance of *intuition as a psychological state*.[1] What is it for someone to have a moral intuition that it is wrong to kill one in order to save five, for example, and what does it matter if they do? For philosophers intuitions are primarily identified by their *putative epistemic and dialectical role*. In particular, intuitions are supposed to play a *foundational* or *quasi-foundational* role in nonempirical justification. They are justifiers that require no further proof or at least initially credible starting points of inquiry. As such, they are not based on theory, but rather constitute data that theories have to account for or explain away.

[1] Sometimes the term "intuition" is also used for the *proposition* that is the *content* of the psychological state. I will leave aside this use here. The adverb "intuitively" and the adjective "intuitive" are used much more broadly and shouldn't be taken to entail that anyone has an intuition (*pace* Cappelen 2012).

So the question is: what if any psychological states are fit to play such a justificatory role and why? Philosophers differ sharply. For *intuitionists*, intuitions are either intellectual appearances, attractions to assent to propositions, or beliefs that result from merely adequately understanding their content. For *coherentists*, intuitions are considered judgments that are inputs to a process of reflective equilibrium. For *intuition skeptics*, in contrast, there is nothing that plays the intuition role – so-called intuitions are just beliefs or inclinations to believe that have no special justificatory status (Williamson 2007; Cappelen 2012).

Psychologists and other empirical scientists, in turn, at least typically think of intuitions as beliefs that result from automatic, nonconscious, and nonrational psychological processing. In this chapter, such psychological processes will be labelled *intuitive processes*. The beliefs that result from them will be called *intuitions** to distinguish them from intuitions in the sense that philosophers use. It turns out to be very important to understanding and addressing philosophical claims made by psychologists and neuroscientists that they are not always talking about the same thing as philosophers when the latter use the word "intuition." Yet at the same time, psychological results may nevertheless be very important for understanding intuitions in the philosophers' sense.

This chapter will begin with an overview of intuitions as understood in empirical moral psychology and briefly examines some claims made on the basis of empirical findings. It will then outline the various philosophical conceptions. The final section looks at how the two pictures might be reconciled.

Intuitions in Empirical Moral Psychology

As noted, psychologists typically define intuitions as beliefs we acquire without (conscious) reasoning (i.e., intuitions*). For example, according to Jonathan Haidt, a moral intuition can be defined as

> the sudden appearance in consciousness of a moral judgment, including an affective valence (good-bad, like-dislike), without any conscious awareness of having gone through steps of search, weighing evidence, or inferring a conclusion. (Haidt 2001, p. 818)

It is an empirical question which of our moral judgments are intuitions* in this sense and which judgments result from reasoning, for example. The primary goal of empirical moral psychology here is to find out to what extent intuitive processes *explain* why people judge as they do and what role they play in moral agency. But both psychologists themselves and experimental philosophers have also drawn normative or epistemic conclusions from these explanations.

Dual Process Theory

It has proven useful in psychology to make a distinction between two kinds of psychological process. Some processes are fast, effortless, nonconscious,

uncontrolled, and non-intentional; often associative or pattern matching and nonlinear; and frequently affective. They are also often contained within relatively self-contained mental "modules" such as visual perception that are innate and typically products of natural selection. These processes form what is often called *System 1* or the Intuitive System. In contrast, the processes that belong to *System 2* or the reasoning system are relatively slow, effortful, conscious and attention-demanding, controlled, intentional, serial, and potentially rational. The evidence in favor of this contrast between conscious and nonconscious thinking is by now overwhelming (see Wilson 2002; Kahneman 2011).

From a philosophical perspective, it is crucial that System 1 comprises of very *heterogeneous* processes. Some System 1 processes are likely to result in false beliefs, especially when triggered outside the context in which they are adaptive. The heuristics and biases approach (Kahneman et al. 1982) has extensively studied such predictably irrational processes. However, other System 1 processes are likely to produce true beliefs. For example, I understand an ordinary English sentence in a flash, as a result of nonconscious processing I can't control. Yet, of course, I *know* what it means. So sometimes the outputs of System 1 are likely to be false, and sometimes they are likely to be true. It all depends on which System 1 processes are at issue and what the circumstances are like. Bearing this point in mind is very important in thinking about the epistemic relevance of intuitive processes.

Intuitions and Explanation

Why do we make the moral judgments we do? One kind of answer to this explanatory question concerns the *proximal* causes of moral judgments – the psychological states and processes that cause moral judgments. They are responses to the agent's (perceived) situation. A further explanatory question concerns the origins of the proximate processes: why do certain situational features trigger certain responses? The answers to this question are *distal* explanations.

It is a signature claim of much recent empirical moral psychology that the proximal causes of many, indeed most, judgments are automatic and often affectively laden intuitive processes, so that many of our moral beliefs are intuitions* (see Pizarro, this volume). Briefly, we're often unable to articulate our reasons, emotion-related areas of the brain are activated when we judge, and we evaluate quickly, constantly, and without taxing working memory. As a rule, System 2 becomes involved only when there's a problem – when intuitions conflict or the social context requires explicit articulation (Haidt 2001). No one denies that *some* moral judgments result from reasoning – though reasoning often serves to rationalize preexisting intuitions* after the fact.

So intuitive processes appear to proximally explain many of our moral judgments. What is the *distal* explanation for the intuitions* that we have? Many contemporary psychologists appeal to the *evolutionary benefits* of intuitions*. For example, according to Haidt's Moral Foundations Theory (Haidt 2012), natural selection has favored the development of six innate modules that produce the

various affective responses underlying intuitions*. Roughly, the story is that groups whose members respond negatively to things like causing innocents to suffer and disrespecting those with high social status and positively to helping those in need or respecting the elders are likely to outcompete groups whose members do not have such responses. Consequently, the genes that program for the adaptive responses become more prevalent by group selection. Different cultures then fine-tune these innate responses in different ways.

For my purposes, the details of this broadly plausible account do not matter. The important questions arise from the assumptions that intuitions* are hardwired and evolutionary fitness-enhancing.

Are Intuitions* Unreliable?

In the psychological literature it is typical to assume that moral beliefs that result from explicit reasoning are epistemically unproblematic. To be sure, from a philosophical perspective this is highly contingent – after all, there is such a thing as bad reasoning and false premises! But what should we think of the epistemic status of intuitions*?

One popular claim is that intuitions* are unreliable, because they result from *affective* processes. The best-known such argument is made by Joshua Greene (e.g., Greene 2008). According to Greene, only *nonconsequentialist* beliefs result from intuitive processes, while consequentialist beliefs are the result of reasoning. On the basis of this, he constructs an *a posteriori* argument for consequentialism (cf. Kauppinen 2013):

1. Empirical investigation shows that nonconsequentialist moral intuitions* are proximately caused by intuitive emotional reactions.
2. Intuitive emotional reactions don't justify the beliefs they cause, because they are sensitive to morally irrelevant features.
3. So, empirical investigation undermines the justification of nonconsequentialist moral intuitions*.
4. Nonconsequentialist moral theory rests crucially on nonconsequentialist intuitions*.
5. So, nonconsequentialist moral theory is epistemically unsupported.

Greene's critics, such as Berker (2009), have pointed out that the second premise is not an empirical or neuroscientific one. But as Greene rightly counters, empirical evidence in favor of the first premise still does crucial work in the argument. Specifically, he believes that it shows nonconsequentialist intuitions* result from negative emotional responses towards using personal force to harm others (Greene et al. 2009). The distal explanation for this is roughly that such reactions facilitated peaceful coexistence in small groups in human prehistory. The evolved "point-and-shoot morality," however, is likely to misfire in modern conditions, so we shouldn't rely on intuitions* in moral thinking (cf. Singer 2005). Greene's openly normative assumption is that whether we use personal force in causing harm is morally irrelevant. As he notes, this is something it is hard for anyone to deny.

There are, however, at least three major problems with this line of argument. First, there are nonconsequentialists who disavow appeal to intuitions about cases, most notably Kantians (e.g., Wood 2011). Even if most people's nonconsequentialist beliefs were based on unreliable gut reactions, it doesn't follow that nonconsequentialist theory isn't true or unsupported, as long as there is some other kind of justification for it. Second, even if consequentialist beliefs result from reasoning, it doesn't follow that they are justified, unless the premises of that reasoning are themselves justified. And at least some of those premises appear to rely on intuitions, such as the intuition that it is better to save more rather than fewer people, at least other things being equal. Nonconsequentialists are free to turn the tables and say that this intuition is a part of an evolved point-and-shoot morality that sometimes gets it right and sometimes doesn't. If, on the other hand, being the product of evolution shows that a moral belief is unjustified – which many now consider a red herring (see, e.g., Kahane 2011) – then the consequentialist is hoist by his own petard.

Finally, many have called into question the specific interpretations of empirical data that Greene offers (e.g., C. Klein 2011). Even if intuitions* are results of an affective process, it has certainly not been shown that all morally relevant emotions are responsive to features that are uncontroversially morally irrelevant. For example, the sort of reactions that classical sentimentalists thought central to morality, such as resentment and gratitude, are responsive to features such as being used as a mere means for another's ends or exceeding expectations. Nothing so far shows they couldn't confer justification to beliefs (see below).

Can Intuitions* Be Reliable?

As I noted earlier, there are System 1 processes that are potentially sources of knowledge. If (some) intuitions* result from some such process, they will be trustworthy. I'll discuss two recent proposals to this effect.

According to what I'll call the *Expert Intuition View*, moral intuitions* *can* be reliable in just the same way as what are called expert intuitions are, provided we have the right kind of training. Allman and Woodward (2008) argue that moral intuitions* are the output of a species of affective social cognition that can be trained to be responsive to moral features by the same sort of implicit learning that teaches nurses to recognize which infants are sick, for example. In this kind of learning, the learner is exposed to cues she may not able to articulate, forms judgments, and receives independent feedback that tells her whether her judgments are on the right track or not – for example, a child's temperature returns to normal in response to treatment (G. Klein 1998). With enough experience, her System 1 delivers functional "intuitions" about what to do.

The chief, and in my view fatal, problem with the Expert Intuition View is that one of the necessary conditions for implicit learning, namely, immediate and unambiguous feedback (see Kahneman and Klein 2009), is missing in the case of morality. If I act on the mistaken intuition* that it's acceptable for me to break

a promise to a student in order to get a bit of rest, what is the equivalent of an infant's fever getting worse? Nothing. Even if moral mistakes reliably have bad consequences for *others*, no one thinks there is reliably a negative signal for the *agent*. People can persist with mistaken moral views quite easily, especially if surrounded by the like-minded.

A different approach to trustworthy intuitions* is provided by the Moral Grammar View (Dwyer 1999; Mikhail 2011; Hauser 2006). According to it, the process that yields moral intuitions* is nonconscious and automatic, but strictly rule-governed and computational rather than associative and affective. This innate moral competence is analogous to Chomsky's universal grammar. Again like linguistic understanding, the rules that govern this System 1 process are inaccessible to ordinary users, but can be articulated by experts, who deduce the existence of rules like the Doctrine of the Double Effect on the basis of observational data about judgments.

This is no place to evaluate Mikhail and Hauser's explanatory theory. Supposing it to be true, what can we conclude about the epistemic status of intuitions*? Mikhail talks freely about knowledge and competence and seems to assume that beliefs that result from exercising competence are somehow correct. But there's a crucial disanalogy to language here: moral judgments purport to represent how things are and are not in any sense "correct" just because they are entailed by *some* system of rules. An error theorist about ethics might happily endorse the Moral Grammar View as showing that we are hardwired to make systematically false moral judgments. So the epistemic status of the Doctrine of the Double Effect, for example, remains a mystery, if this explanation is correct.

Intuitions in Moral Philosophy

Although there is some controversy about how common appeals to intuition are in philosophy in general (Cappelen 2012), there is little doubt that they play a major role in contemporary normative ethics. Intuitions (or intuited propositions) about either particular cases or general principles are treated as presumptively valid starting points of ethical inquiry. As W.D. Ross put it, "the moral convictions of thoughtful and well-educated people are the data of ethics just as sense-perceptions are the data of a natural science" (Ross 1930/2002, p. 41). Normative theories typically aim to capture intuitions or else find some way of undermining the authority of a particular intuition. But views about the nature and importance of intuitions differ widely.

Self-Evidence Intuitionism

The classical intuitionist view is that certain moral truths are *self-evident*, much in the way that mathematical axioms are to those who understand them. (Sometimes the term "intuitionism" is also used for a related metaphysical thesis that moral properties are nonnatural, but this chapter will focus on the epistemological use.) Here's Ross:

> That an act *qua* fulfilling a promise, or *qua* effecting a just distribution of good . . . is *prima facie* right, is self-evident; not in the sense that it is evident from the beginning of our lives, or as soon as we attend to the proposition for the first time, but in the sense that when we have reached sufficient mental maturity and have given sufficient attention to the proposition it is evident without any need of proof, or of evidence beyond itself. It is evident just as a mathematical axiom . . . is evident (Ross 1930, pp. 29–30).

On a natural reading, for me to have the intuition that fulfilling a promise is *prima facie* right is for me to find the proposition evident simply on the basis of understanding it properly and attending to it. According to Robert Audi's contemporary reformulation, an intuition is a cognitive state whose content one doesn't infer from what one believes or any theory but which one forms on the basis of an adequate understanding of the intuited proposition (Audi 2004, pp. 33–36). Its content is a *self-evident* proposition. A proposition is self-evident "provided an adequate understanding of it is sufficient both for being justified in believing it and for knowing it if one believes it on the basis of that understanding" (Audi 2004, p. 49).

Audi thus considers intuitions as *beliefs* that are individuated by their distinctive *justification and aetiology*. Ernest Sosa's (2007) related rationalist view in general epistemology differs in that he considers an intuition to be an *attraction to assent* to a proposition rather than a belief. This is because we can have an intuition that *p* even if we know that *p* is false – for example, all the lemmas of a paradox are intuitive. On either picture, given that mere understanding suffices for knowing their content, intuitions are instances or sources of a priori knowledge. Given that their content is not tautological, they are sources of knowledge about *synthetic* truths.

Nonmoral examples of putatively self-evident propositions include *Nothing is both red and blue all over*, *No vixens are male*, and *The existence of great-grandchildren requires at least four generations of people*. Moral intuitionists differ on what kind of moral propositions are self-evident. For Sidgwick, only the most *fundamental moral principles* can lay claim to self-evidence. According to him, they are that "the good of any one individual is of no more importance, from the point of view (if I may say so) of the Universe, than the good of any other" and that "as a rational being I am bound to aim at good generally" (Sidgwick 1907, p. 382). From these he infers the truth of a form of Utilitarianism.

Ross, in contrast, believes that several *mid-level moral principles* are self-evident. For example, he believes it is self-evident that we have (defeasible) moral reason to keep our word, match rewards to desert, be grateful to benefactors, to refrain from injuring others, and to benefit others. These are among considerations that always weigh in favor or against performing an action. An agent's overall or final duty in a particular case is a function of these *pro tanto* reasons. Finally, while most intuitionists agree that *verdicts about particular cases* cannot be self-evident, H. A. Prichard and moral particularists deny this. We can just see what the right thing to do in a particular situation is. Indeed, Prichard thought this is epistemically prior: "If I cannot see that I ought to pay this debt, I shall not be able to see that I ought to pay a debt" (Prichard 2002, p. 4).

Recent work by Audi, Shafer-Landau (2003), and others has dispelled many standard objections to the Self-Evidence View. There is no appeal to a special faculty of intuition, only ordinary understanding. A proposition can be self-evident even if some people who understand it don't regard it as self-evident, certain, or even true – after all, all that matters is that they *would be justified* in believing it on the basis of mere understanding. Nor need a self-evident proposition be obvious, as adequate understanding may take time and effort. Given the preceding, it is not surprising if people *disagree* about self-evident propositions – even if they adequately understand them, they may be led to deny them as a result of indoctrination, bad theory, or self-interest. A person suffering from such issues might sincerely believe that she has an intuition – but insofar as her belief or attraction isn't justifiable by mere understanding of the content, she is mistaken about its nature.

Nevertheless, challenges remain. Although epistemological intuitionism is logically independent of nonnaturalist moral metaphysics, they are de facto allies. After all, if moral facts were natural facts, why couldn't we come to know them the way we come to know other natural facts? But if moral facts are nonnatural and thus causally inefficacious, while intuitions are psychological states with causal histories governed by natural laws, it would have to be a fantastic cosmic coincidence for the contents of the intuitions to align with the nonnatural facts (Bedke 2009). Further, mere adequate understanding of the content is supposed to justify belief in the self-evident proposition. Sometimes this makes sense. What it is to understand the concept of a vixen is, at least in part, to know that it does not apply to males. So it is no surprise that merely understanding it suffices for knowing the *conceptual* or *analytic* truth that no vixens are male. But how can mere understanding reach to *synthetic* truths that are not about relations between concepts? That turns out to be very hard to account for (for recent attempts, see Jenkins 2008 and Bengson 2010).

Seeming-State Intuitionism

In general epistemology, it has recently become popular to think of intuitions as intellectual appearances or seemings (Bealer 2000; Chudnoff 2011). This view has adherents in moral epistemology as well, as Michael Huemer's definition of moral intuition shows:

> An intuition that p is a state of its seeming to one that p that is not dependent on inference from other beliefs and that results from thinking about p, as opposed to perceiving, remembering, or introspecting. (Huemer 2005, p. 102)

Huemer's definition has two parts: an intuition is (a) a seeming and (b) the result of merely thinking about the proposition. Seemings or appearances in general are *non-doxastic*, propositionally contentful states: it may seem to me that the stick in the water is bent, even though I do not *believe* that it is. They have a *presentational phenomenology*: when we have them, it's as if we're directly presented with their objects or truth-makers. Consequently, they are *compelling*: they attract assent to their content and appear to rationalize belief. Some such seemings are

perceptual, such as my visual experience of having a computer in front of me. But others are, according to seeming-state intuitionists, *intellectual*: they result from merely thinking about the proposition. They claim that merely thinking about killing one in order to save five can give rise to a non-doxastic, presentational, and compelling experience of moral wrongness.

Suppose that when I merely think about it, cheating on my spouse seems morally wrong to me. Does this justify my believing so? Seeming-state intuitionists tend to subscribe to a view about justification called epistemic liberalism (Bengson 2010). According to this view, we are justified in taking things to be as they appear to be, unless we have sufficient reason to doubt the appearances. Not every experience is a seeming in the specified sense, so the view doesn't license belief in just anything we dream or fantasize about. But when it comes to genuine seemings, we're not epistemically blameworthy for taking them at face value, other things being equal.

Walter Sinnott-Armstrong (2006) argues against this kind of view in ethics. According to him, empirical evidence shows that other things are not equal: the way things seem to us, morally speaking, is often biased by partiality, beset by peer disagreement, clouded by emotion, subject to framing effects, and influenced by disreputable sources like religion. Such factors, in general, give us reason to doubt appearances of a particular kind, so we can't take them at face value without some sort of further confirmation. But the need for further confirmation, Sinnott-Armstrong says, means that intuitions are unfit to play a foundational role in justification, so intuitionism is false.

Coherentism and Intuitions

What are often described as intuitions also play a crucial role in the best-known coherentist approach to moral epistemology, the method of *reflective equilibrium* (Rawls 1971; Daniels 1979). Here is how Rawls describes it:

> People have *considered judgments* at all levels of generality, from those about particular situations and institutions up through broad standards and first principles to formal and abstract conditions on moral conceptions. One tries to see how people would fit their various *convictions* into one coherent scheme, each considered judgment whatever its level having a certain *initial credibility*. By dropping and revising some, by reformulating and expanding others, one supposes that a systematic organization can be found (Rawls 1974, p. 8, my emphasis).

As I have highlighted, Rawls talks about considered judgments and convictions as the initially credible (but potentially revisable or dispensable) starting points of moral inquiry. In this lightweight sense, intuitions need not be any special sort of mental state or have any particular kind of aetiology. The emphasis on *considered* judgments rules out unreflective gut reactions, however.

While the deflationary aspect of Rawlsian intuitions has its attractions, it also raises an immediate epistemic question. Why should the mere fact that we believe something yield *any* initial credibility to the believed proposition? Precisely because the aetiology of the beliefs doesn't enter the picture, considered ideological

or self-serving judgments seem to start out with the same status as rational insights. Coherentists might respond by waging that such beliefs fall out in the process, but insofar as it is path dependent (i.e., the outcome depends on what the inputs are), there is no guarantee that the outputs of reflective equilibrium aren't systematically biased.

Coherentists might appeal to the notion of *wide* reflective equilibrium, in which psychological, sociological, and other empirical facts are brought into the balancing act. This might rule out beliefs with some intuitively problematic aetiologies, such as beliefs based on knee-jerk reactions or sensitive to the use of personal force (see the discussion of Greene above). But why? Because these causal histories typically result in beliefs that do not fit with the rest of our moral beliefs. This means that if our moral beliefs are distorted to begin with, widening the reflective equilibrium won't help. The ideologically brainwashed will regard the process we regard as brainwashing as conducive to true beliefs.

Perhaps the best response to worries about both seeming-state intuitionism and coherentism is provided by Mark van Roojen (forthcoming). He acknowledges that the kind of considerations Sinnott-Armstrong puts forward may mean that intuitions don't suffice to justify belief on their own. But when a proposition is *both* the content of a moral intuition *and* coheres with other intuitive propositions, belief in it will be justified. The initial credibility provided by intellectual appearance is, as it were, confirmed by coherence. Since reflective equilibrium is applied selectively only to appearance-based beliefs, low-quality inputs to the balancing process are filtered out at least to some degree.

Conclusion

How do the psychological and philosophical views of moral intuitions relate to each other? Could both disciplines learn something from each other? Before trying to answer these questions, here is a map of the different views of intuition that discussed here:

As Table 11.1 makes obvious, many intuitions* are not intuitions in the philosophical sense. This has several consequences for contemporary debates in empirically informed ethics or experimental philosophy.

First, as has been pointed out, not all System 1 processes are epistemically equal. One kind of intuitive process that is particularly likely to issue in false beliefs is quick gut reaction. But for philosophers, it is emphatically not the case that the truth of an intuited proposition supposed to be manifest in a quick flash. It is *immediate* only in the sense that its justification is not mediated by some further, itself justified belief. Coming to an adequate understanding of a proposition or thinking about a thought experiment is an effortful, System 2 process that may take time, often compared to what it takes to appreciate a work of art (e.g., McMahan 2013). As Audi (2004) puts it, an intuition can be a conclusion of *reflection*, although it can't be a conclusion of *inference*. This kind of reflection is not the sole privilege of philosophers, but it is one of the things they're trained to do. This gives a positive reason to regard philosophers' intuitions as superior.

Table 11.1 Views about moral intuition

	Type of mental state	*Aetiology*	*Claimed epistemic standing*
Psychology	Belief	System 1	Most consider dubious
Self-evidence intuitionism	Belief or attraction to assent	Mere adequate understanding of content, which also justifies belief	Constitutes or is a source of knowledge of nonnatural facts
Seeming-state intuitionism	Appearance/seeming/presentation	Merely thinking about the content	Justifies belief in the absence of reason to doubt
Coherentism	Belief/conviction	Reflection, consideration	Initial credibility

Second, it is often claimed that surveys or questionnaires reveal people's moral intuitions about particular cases so that by varying the cases and performing statistical analyses, we can discover what ordinary people's intuitions are sensitive to (Kahane 2013). But as John Bengson (2013) has pointed out, this is simply not a valid inference. Even if responses reflect intuitions*, it doesn't follow that the subjects have an intuition in any sense that interests philosophers. This at least limits the usefulness of survey studies and complicates any empirical study of intuitions.

Future Directions

Although not all intuitions* are intuitions in the philosophical sense, the latter are nevertheless the outcome of some intuitive process rather than reasoning or inference. Could empirical evidence about the nonconscious functioning of brain and mind help understand intuitions and their role? I believe it is going to be one important ingredient in the mix. This chapter will finish by briefly sketching the case for thinking of intuitions as *manifestations of moral sentiments* (see Kauppinen forthcoming).

Start with the observation that moral intuitions appear to have a *distinctive and diverse phenomenology*. When something *seems* wrong, it often *feels* wrong – even if one *believes* it is right. This suggests that intuitions are non-doxastic experiences, as seeming-state intuitionists think, but not the same kind of experience as other intuitions. Second, moral seemings can directly *motivate* us to act and react. This is clearest in cases like Huck Finn's lying to slave catchers: although he didn't *believe* that it was the right thing to do (it went against everything he was taught), it nevertheless *felt* like the right thing, and this was sufficient to move him to act. Third, note that apparently manipulating the subjects' emotions results in change in their intuitions (e.g., Valdesolo and di Stefano 2006), while it is unlikely to change the mathematical or other run-of-the-mill intellectual intuitions.

All these special features of moral intuitions are readily accounted for if they are emotions. Which emotions? Those that manifest moral sentiments. Sentiments are dispositions to feel, act, think, and believe (cf. Prinz 2007). The sentiment of liking one's dog manifests itself in delight on seeing the animal, sadness when it is ill, noticing when its favorite food is for sale, desire to buy the food, and so on. The sentiment of moral disapprobation towards cheating on one's spouse manifests itself in anger towards someone who cheats on his spouse, guilt when one thinks of doing it oneself, desire to refrain from acting on certain desires, and so on. In this context, Kauppinen (forthcoming b) has argued the emotional manifestations of the sentiment constitute moral appearances: the anger you feel towards the unfaithful husband *presents* his action as morally wrong and attracts you to *believe* that it is morally wrong, while also having a distinctive phenomenal feel and motivational role. Since these emotions constitute moral seemings, they confer defeasible initial credibility to their contents just as other seemings do.

But aren't emotions subject to general epistemic defeaters, due to their characteristic fickleness and partiality? In this respect, not all emotions are created equal. *Canonical moral sentiments* are felt from what Hume called "The Common Point of View" – roughly speaking, they result from a process of impartially empathizing with the hedonic states and reactive attitudes of those affected by the actual or hypothetical action. When my anger or guilt is based on this kind of sentiment, the generic reasons for doubting emotional appearances are absent – the emotional reactions aren't fickle, rash, partial, or ill-informed. Further, such responses are not sensitive to what everyone agrees are morally irrelevant features, such as mere physical distance, but rather to features like being treated as mere means or not receiving equal reward for equal contribution, which are plausibly morally relevant.

So let's go back to the questions we started out with. I have the moral intuition that it is wrong for a doctor to grab a random person off the street and take his vital organs to save five others. According to the view just sketched, this intuition is trustworthy when it consists in an emotional response that I have when I merely think about the case in the canonical way – not just understanding the proposition but also imagining myself in the shoes of those affected by the action. This suggestion is compatible with the well-supported empirical hypothesis that emotions play a crucial causal role in moral judging. Although the response itself results from a System 1 process, it may be preceded by conscious, System 2 effort to reflect on the situation and empathize with different perspectives. Given that the sentimental intuition presents the action as wrong and isn't subject to standard defeaters, it is fit to play at least a quasi-foundational role in moral justification. So it seems that if at least some moral intuitions consist in a sharply delimited kind of emotional response, it will be possible to go fairly far in reconciling the psychological and philosophical conceptions without skeptical consequences.

The Half-Life of the Moral Dilemma Task: A Case Study in Experimental (Neuro-) Philosophy

Abstract

The pioneering neuroscience of moral decisions studies implementing the moral dilemma task by Joshua Greene and colleagues stimulated interdisciplinary experimental research on moral cognition as well as a philosophical debate on its normative implications. This chapter emphasizes the influence these studies had and continue to have on many academic disciplines. It continues with a detailed analysis of both the traditional philosophical puzzle and the recent psychological puzzle that Greene and colleagues wanted to solve, with a special focus on the conceptual and experimental relation between the two puzzles. The analysis follows the fundamental logics essential for psychological experimentation that is also employed within cognitive neuroscience: the logics of defining a psychological construct, operationalizing it, formulating a hypothesis, applying it in an experiment, collecting data, and eventually interpreting them.

In this manner, this chapter exemplifies an analytical structure that can be applied to many other examples in experimental (neuro-) philosophy, here coined "The Experimental Neurophilosophy Cycle." This chapter eventually discusses how the empirical findings and their interpretation, respectively, are related back to the original philosophical and psychological puzzles and concludes with conceptual as well as experimental suggestions for further research on moral cognition.

Introduction

> Paradoxes such as this mean job security for philosophers. They've been debating them for decades but have been unable to come up with a logical reason why sometimes it's OK to kill one person to save five, whereas other times it's not. Now, an interdisciplinary team has offered its philosopher colleagues a helping hand. (Helmuth 2001, p.1971)

This excerpt from the report that accompanied the pioneering neuroscience of moral decisions study by Joshua Greene and colleagues in *Science* (Greene et al. 2001) has an implication that may be disconcerting for ethicists and moral philosophers: If it is true that the moral dilemmas that so far resisted clear philosophical solutions but provided job security for these scholars can now be explained by psychologists and neuroscientists, then do we still need ethicists and moral philosophers? Or, put more reluctantly, is it possible that we will need them less in the future than we did in the past? This chapter, broadly speaking, is about the provocative question whether and in how far the tasks carried out by philosophers are likely to be replaced by scholars from other disciplines, and it will discuss this on the basis of the said findings of moral neuroscience, moral physiology (Schleim 2008), neuroscience of ethics, or however one would like to call this field of research.

The debate concerning the relation between philosophy understood as a quest for conceptual clarification, logical truth, or normative conclusions and the empirical disciplines has a long tradition. With the separation of psychology around the turn of the previous century and more recently with advances in the cognitive neurosciences, scholars began to investigate questions concerning consciousness and mind independently from their philosophical roots and employing empirical methods such as experimentation, surveys, and systematic observation.

Both within and outside of philosophy, different views on this relation exist: Investigating language practices of the neurosciences, one can emphasize the importance of philosophically clarifying empirically essential concepts in order to avoid confusion (Bennett and Hacker 2003); considering the brain as the primary organ with which we think and thus philosophize, one can argue that our neurobiology essentially limits our possible experiences which in turn has implications for our philosophical theories (Northoff 2004). Others remark skeptically that thousands of years of "philosophical speculation" on, for example, the phenomenon of consciousness have not been very informative and suggest to leave philosophical issues aside in order to face and possibly solve the challenge empirically (Crick and Koch 1998).

Particularly with regard to socially widely relevant issues concerning normative practices, such as the possibility of free will, moral responsibility, and the justification of the penal code, there even was a competition on whether empirical research or non-empirical argumentation has the final say (Libet 1985, and subsequent comments Roskies 2006a; Sie and Wouters 2010). Related to that domain, some philosophers used empirical cases to gain meta-ethical insight, such as in the plausibility of motivational internalism, the thesis that moral beliefs are intrinsically motivating (Levy 2007; Roskies 2006b). The probably most popular and until today widely cited example (see Fig. 12.1) used functional Magnetic Resonance Imaging (fMRI), a method to record brain signals in order to interpret them psychologically (see also ▶ Chap. 40, " Neuroimaging Neuroethics: Introduction"), not only to investigate why common people respond to moral dilemmas in the way they do, but also to explain why moral philosophers traditionally held incompatible views on these matters (Greene et al. 2001, 2004).

While others discussed the possibilities, prospects, and limitations of experimental philosophy generally (Alexander 2012; Knobe and Nichols 2008; *Philosophical Psychology* Special Issue 2010 Vol. 23 No. 3 & 4), this chapter deals with this popular investigation of moral dilemmas, its experimental preconditions, design, and psychological as well as philosophical interpretation. In this respect, the chapter is a case study in experimental (neuro-) philosophy, but its stepwise manner of analysis can – and

perhaps even should – be applied to other cases, too. Based on this analysis, the author will argue that, first, because this kind of experimentation presupposes certain conceptual definitions, it cannot replace philosophical conceptual clarification entirely; second, because it presupposes methodological conventions and decisions, its results are provisional; and third, the necessity of interpreting empirical findings with regard to research questions implies an amount of tentativeness. From this it follows that experimental (neuro-) philosophy – or empirical research in general – cannot replace philosophy but at best inform it and at worst confuse it. Based on this analysis, the author will also argue for the need of a critical philosophy of experimentation.

More concretely, the stepwise structure of the analysis consists in discussing and answering the following questions with respect to the moral dilemma task designed and applied by Joshua D. Greene and colleagues (Greene et al. 2001, 2004): First, what were the questions they wanted to answer? Second, how did they choose to answer the questions? Third, how did they answer the questions? Fourth, can the answers to the previous three questions be upheld after a critical discussion? That is, the analysis covers the fundamental logics essential for psychological experimentation that is also employed within cognitive neuroscience: the logics of defining a psychological construct, operationalizing it, formulating a hypothesis, applying it in an experiment, collecting data, and eventually interpreting them.

This chapter does not deal with the normative implications of such experimentation directly, an issue debated controversially elsewhere (Berker 2009; Greene and Cohen 2004; Greene 2008; Kahane 2013; Kauppinen, this section; Rini, this section; Singer 2005). Obviously, though, this analysis of the experiments' presumptions, findings, and interpretations is indirectly relevant to that discussion.

What Were the Questions They Wanted to Answer?

Greene and colleagues (Greene et al. 2001, 2004) derived their experimental idea from a famous philosophical puzzle, the moral question whether it is right (morally permissible or, stronger, perhaps even obligatory) or wrong (morally forbidden) to save the lives of a number of people when this requires an action that implies – more or less directly – the death of a smaller number of people, typically just one person (Foot 1978; Thomson 1986). Exemplary cases are the famous *trolley* (whether to divert a trolley by throwing a switch such that it will run over and kill one person instead of five), *footbridge* (whether to push a large man from a footbridge and thus killing him in order to stop a trolley that would otherwise run over and kill five persons), and *infanticide* (whether to smother one's crying baby to prevent enemy soldiers from finding and killing a group of hiding people, including the baby) dilemmas. Different answers to these questions are especially puzzling from a consequentialist's point of view that evaluates the moral status of an action exclusively with respect to the consequences – here: the number of people dead and alive – of an action; they might be less puzzling from a practical legal perspective, for example, where the first case rather resembles an instance of negligent homicide, the second manslaughter, and the third self-defense.

However, Greene and colleagues did not address the philosophical puzzle in the first place, but rather a psychological variant thereof: Why do many people commonly decide that it is right to sacrifice the few for the good of the many in some cases, particularly the trolley dilemma, but not others, particularly the footbridge dilemma? They proposed that different reactions may be due to people's emotional responses and capacities to deal with them cognitively, processes whose effects should be measurable in behavior and brain. For this reason, Greene and colleagues designed an experiment employing moral dilemmas of different kinds, the factor that is manipulated by the experimenter and called the *independent* variable, while recording reaction time and brain signals using fMRI, the *dependent* variables. In their second study (Greene et al. 2004), they addressed the more specific question which processes correlate with a particular kind of judgment, the one they called "utilitarian," when contrasted with "non-utilitarian" judgments. Since this classification has been contested (see below), "utilitarian," "consequentialist," and "deontological" will always be used in quotation marks in order to distinguish the experimental concepts from the more classical understanding proposed by moral philosophers.

In the long run, Greene and colleagues related their findings with regard to the psychological puzzle back to the original philosophical puzzle, particular the question what generally drives moral judgments of a deontological, that is, essentially duty-based, kind, as compared to moral judgments of a consequentialist, that is, exclusively consequence-based, kind (Greene et al. 2004; Greene 2008), a question that is discussed controversially until today (Paxton et al. in press; Kahane et al. 2012). In the course of this debate, the psychological answer was even used to speculatively explain why *philosophers* developed different moral accounts (Greene et al. 2004; Greene 2008). However, as stated in the introduction, the focus of this chapter is the psychological puzzle and how the researchers tried to answer it.

How Did They Choose to Answer the Questions?

Greene and colleagues introduced an experimental distinction that they thought reflected essential differences between trolley-type and footbridge-type cases, namely, the distinction between moral-*personal* and moral-*impersonal* dilemmas. For experiments measuring behavioral or brain responses, it is often insufficient to use just a few stimuli, in an extreme case only one, because the data tend to have a lot of variability, partially attributed to random processes called "noise." When repeating a measurement a sufficient number of times, in a sufficient number of subjects, the idea is that an average measure of the collected data should represent the "signal," that is the pattern truly related to the experimental conditions and not random fluctuations or other uncontrolled features. That is the reason why it would have been insufficient to just present the two or three original dilemmas, as they had been described and discussed before intensively by philosophers, to the experimental subjects, and general categories had to be developed.

The researchers stated that they considered their personal-impersonal-distinction for the experimental categories by no means definitive and primarily chose it for its usefulness, that is, for pragmatic reasons (Greene et al. 2001, 2004). However, this distinction was the central part of their operationalization to answer the psychological puzzle, because they expected that moral-personal dilemmas reflecting footbridge, where many people would not endorse the sacrifice, would be accompanied by signs of emotions in contrast to the moral-impersonal dilemmas reflecting trolley, where most would endorse the sacrifice. This distinction, as it was operationalized for the experiment, consisted of the following three requirements guaranteeing that the sacrifice in the moral-personal category would be brought about in an "up close and personal" manner (Greene et al. 2004; Greene 2008): First, the action would reasonably be expected to lead to serious bodily harm; second, this harm would not only consist in a deflection of a threat from one party to another, implying, in the researchers' opinion, a certain kind of agency; and third, this harm would be inflicted on a particular person or members of a particular group. Cases meeting these three criteria were considered as moral-personal dilemmas, otherwise as moral-impersonal.

The experimental methods chosen to provide the data to answer the psychological puzzle were an fMRI scanner, recording a primarily blood-oxygenation-related signal in the brain that is often considered a proxy for neural activation, though the correct interpretation of this signal is still a matter of basic research (Logothetis 2008; Schleim and Roiser 2009), in which the subjects, groups of circa ten to forty undergraduate students, were shown the dilemma texts, circa twenty per condition on a computer screen and had to use buttons to provide their answers; the time needed to provide these answers was also recorded. Note that because the experiment was carried out in slight variations for the publications 2001 and 2004, these figures represent approximations, which may be neglected for the purpose of this discussion.

For the more detailed question regarding the difference between "utilitarian" and "non-utilitarian" judgments, the researchers compared responses within a subclass of their stimulus material, namely, difficult moral-personal dilemmas, where "difficult" means that subjects needed more time for their answers compared to the other cases. When subjects endorsed the sacrifice action, Greene and colleagues considered this a "utilitarian" judgment, otherwise "non-utilitarian" (Greene et al. 2004), later discussed as "consequentialist" and "deontological" judgments, respectively (Greene 2008).

How Did They Answer the Questions?

Using a statistical model into which Greene and colleagues entered the respective experimental data (such as the different dilemma types and subjects), they calculated statistical maps that yielded significant differences in a number of brain areas previously associated with emotion, such as the medial frontal gyrus or posterior cingulate gyrus, or with working memory, such as the middle frontal gyrus or the parietal lobe. To understand these differences better, they carried out a further statistical analysis directly comparing the statistical values within the different areas for the moral-personal in contrast to the moral-impersonal condition (for a visualization of many

of these brain areas, please see the ► Chap. 9, "The Neurobiology of Moral Cognition: Relation to Theory of Mind, Empathy, and Mind-Wandering" in this section). This demonstrated that the recorded brain signals within the emotion-related areas were relatively higher during the moral-personal than the moral-impersonal condition, and relatively lower in the working-memory-related areas. A similar statistical analysis for the response times showed that subjects, on average, took significantly longer to endorse a sacrifice in the moral-personal condition – almost seven seconds in contrast to only five when not endorsing the sacrifice – and that the difference in response times for the moral-impersonal condition was not significant (Greene et al. 2001; but see the discussion with respect to the re-analysis of the response time data by McGuire et al. 2009 below). In an analogous analysis for their second study, they could also relate both amygdalae, left and right, structures often associated with emotion, with the moral-personal condition (Greene et al. 2004).

For the more specific psychological puzzle, the brain signals related to "utilitarian" judgment, Greene and colleagues carried out so-called region-of-interest and whole-brain analyses. The former restricted the subsequent statistical tests to those areas that had previously been related to difficult moral-personal judgments compared to easy ones, that is, moral-personal cases for which the subjects needed more time to give their response; the latter tested for statistical differences within the whole brain, independent of previous analyses. In this manner, the "utilitarian" judgments were related to significantly higher brain signals in the posterior cingulate, superior/middle frontal gyrus, which they subsumed under the broad concept dorsolateral prefrontal cortex (DLPFC), precuneus, inferior parietal lobe, lingual gyrus, inferior parietal lobe, and inferior, middle, and superior temporal gyrus (Greene et al. 2004).

In the light of these findings, Greene and colleagues suggested that differences in emotional processing indeed provided the explanation for people's different moral judgments, and thus also the solution to the psychological puzzle: As they expected, reading moral-personal dilemmas and taking a judgment on them correlated with significantly higher activation in brain areas associated with emotion; the reaction time pattern suggested that those who endorsed the sacrifice of the few for the lives of the many had to overcome their emotional reaction, which took more time, in contrast to those who did not endorse these actions; and, finally, those who did so and thus took the "utilitarian" decision had significantly higher activation in the DLPFC, related to cognitive control (Greene et al. 2001, 2004).

This proposed solution to the psychological puzzle was then eventually related back to the original philosophical puzzle, also employing an evolutionary account of brain and psychological development: "We propose that the tension between the utilitarian and deontological perspectives in moral philosophy reflects a more fundamental tension arising from the structure of the human brain. The social-emotional responses that we've inherited from our primate ancestors [. . .] undergird the absolute prohibitions that are central to deontology. In contrast, the 'moral calculus' that defines utilitarianism is made possible by more recently evolved structures in the frontal lobes that support abstract thinking and high-level cognitive control" (Greene et al. 2004, p. 398). This was also interpreted to suggest that classical deontological moral philosophies such as the one proposed by Immanuel

Kant were actually not based in reason, as commonly believed, but instead in post hoc rationalized emotional responses (Greene et al. 2004; Greene 2008).

Discussion of the Answers to the Three Previous Questions

The previous sections covered the full “experimental neurophilosophy cycle” (see Fig. 12.2), starting out with the philosophical puzzle that inspired Greene and colleagues, how they translated this into a psychological puzzle, the psychological constructs and hypotheses they formulated, their operationalization, (some of) the data they collected in their experiments, the subsequent analysis/results, and eventually how they interpreted them, relating the data back to their original psychological and philosophical puzzle.

The illustration emphasizes the different steps in the cycle, with subsequent steps each depending on the previous ones. Figuratively speaking, just like the strength of a chain depends on its weakest link, so does the strength of the experimental neurophilosophy cycle depends on the weakest translational and methodological processes between the steps. For example, if the formulation of the psychological puzzle missed the essential philosophical points, then the research could still be psychologically intriguing, yet hardly be philosophically relevant. One central issue here is what kind of philosophical difference the moral-personal-impersonal-distinction reflects, the strategy Greene and colleagues used to provoke emotional reactions in their subjects and see how they affect their judgments. The experimenters conceded that this distinction was provisional, particularly chosen for pragmatical reasons (Greene et al. 2001, 2004). Indeed, Greene later explained that he no longer believed that the three criteria – serious personal harm that is not merely deflected – were adequate (Greene 2008). Yet, this operationalization was an essential precondition for the answer to the psychological puzzle that emotion drives judgments in the moral-personal cases like footbridge, but not in the moral-impersonal ones like trolley, and research trying to understand which morally salient psychological features are reflected in these stimulus categories continues (Waldmann et al. 2012). This critique need not affect the answer to the particular psychological puzzle concerning the “utilitarian” versus “non-utilitarian” distinction, though, since the analysis comparing these different kinds of judgments was confined to the (difficult) moral-personal cases only, and was thus independent from the contested personal/impersonal distinction.

Joshua Greene removes his psychological answer from the philosophical puzzle in his later work, understanding “consequential” and “deontological” judgments in a functional manner, indeed believing that “it is possible that philosophers do not necessarily know what consequentialism and deontology really are” (Greene 2008, p. 37). According to his functional understanding, it was particularly the disagreement between “consequentialists” and “deontologists” that allowed to distinguish them, namely, in such a manner that “consequentialistic” conclusions characteristically favored saving more lives at the costs of fewer lives, whereas “deontological” conclusions characteristically considered this as wrong despite the benefits.

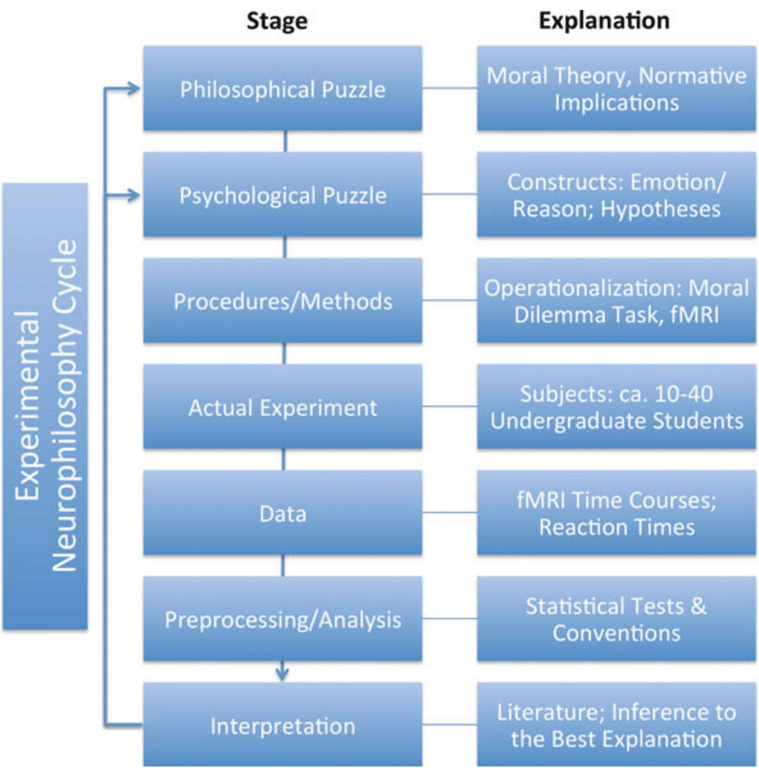

Fig. 12.2 The experimental neurophilosophy cycle: How Greene and colleagues translated their philosophical puzzle into a psychological one and finally relate their experimentally gathered data back to the original psychological and philosophical puzzles by means of their interpretation. This stepwise pattern of analysis can be applied to many examples in experimental (neuro-) philosophy

An experimenter can of course propose his or her own operationalizations, but the functional definition suggested in this case carries the risk of raising problems when linking the findings subject to that operationalization back to the original psychological and philosophical puzzle (Berker 2009; Kahane and Shackel 2010; Kamm 2009; Schleim and Schirmann 2011). That is, linking the psychological and the philosophical puzzle then carries the risk of committing an equivocation, a fallacy that while an argument looks consistent, it is in fact not because the meaning of concepts – here: "consequentialistic" and "deontological" – has essentially changed.

In their second study, Greene and colleagues proposed two psychologically necessary conditions for a judgment on "utilitarian" grounds, namely, abstract reasoning constituting a "utilitarian" analysis and the engagement of cognitive control enforcing the outcome of this analysis against competing, particularly emotional, pressures (Greene et al. 2004). They argued that they indeed found brain activities reflecting these psychological processes, but it may be doubted whether their presence alone is sufficient to identify the judgments as "utilitarian,"

given that a deontological analysis following Kant's categorical imperative literally, essentially includes the following: testing whether an action's maxim can be willed without contradiction to become a universal law (Kant 1785). This test certainly requires abstract reasoning, too, and favoring this action, for example, accepting the death of a dear one when not sacrificing a stranger to save his or her life, requires enforcing this outcome against competing, particularly emotional, pressures. Agreement on necessary and sufficient conditions of investigating judgments accurately reflecting influential moral theories is yet to be found, and it is thus not surprising that the controversial debate continues (Kahane et al. 2012; Paxton et al. in press).

The spatially localized brain activation found by Greene and colleagues cannot prove beyond reasonable doubt that subjects making a "utilitarian" judgment do so by employing abstract reasoning and cognitively controlling an emotional response. The reason for this is the general finding that the common psychological ontology – including central constructs such as "emotion" and "reason" – does not map clearly to brain areas, strictly associating one psychological construct with one brain area or one brain area with one psychological construct (Anderson 2010; Poldrack 2010). Meta-analyses of fMRI data show that all brain areas have a substantial amount of psychological diversity (Anderson and Pessoa 2011); even finding brain activation in a region like Broca's area in the prefrontal cortex that is classically considered to be highly functionally specific for language processing only adds relatively weak evidence to the interpretation that during a language task language processing was indeed occurring (Poldrack 2006). Accordingly, the presence of emotion processing cannot be inferred from statistically significant findings in a particular brain area (Pessoa 2008), not even the amygdalae (Pessoa and Adolphs 2010). At the current stage of knowledge, fMRI cannot be used as a "mind reading device" establishing the presence of a particular psychological process and perhaps it will never be (Logothetis 2008; Schleim and Roiser 2009).

This does not mean that these findings provide no information with regard to the psychological puzzles, but that a proper statistical account has to be employed that also considers, for example, experiments involving non-emotional tasks that correlated with the same brain patterns (Poldrack 2006). Greene's defense that his findings are compatible with a dual-process model encompassing both, quick emotional and slow deliberative approaches towards moral problems (Greene 2008, 2009; but see also Helion and Pizarro, this section; Kahane 2012), is in itself not very informative when these results may also be compatible with another one of the many other psycho-neurobiological accounts of moral cognition (Moll et al. 2005).

In addition, there is also contradicting evidence, such as the presence of relatively higher brain activation in areas such as the medial prefrontal cortex or the posterior cingulate during "utilitarian" judgment (see above; Greene et al. 2004; Moll and de Oliveira-Souza 2007) that the authors themselves related to emotional processing previously (Greene et al. 2001); and essential findings such as the emotional interference effect (see above; Greene et al. 2001) could not be replicated independently (Moore et al. 2008) and were related to poorly defined experimental stimuli in a re-analysis of the original data: When excluding the bad stimuli the response time

pattern originally suggesting the emotional interference disappeared, undermining the idea that the difference in judgments between moral-personal and impersonal dilemmas is driven by emotional influences (McGuire et al. 2009). These considerations do not call into question that experimental (neuro-) philosophy can be fruitful for the empirical sciences as well as philosophy, but suggest that it will be difficult and require both, conceptual clarification and further experimentation, in order to relate data to the respective psychological and philosophical puzzles.

Independent of the philosophical and psychological puzzles discussed in detail in this chapter, Greene himself speculated that the terms "deontology" and "consequentialism" refer to psychological natural kinds (Greene 2008). This suggests that while moral philosophers, in his view, may be wrong about the meaning of these moral theory concepts, empirical research might discover a natural essence allowing us to distinguish between these two (and possibly further) kinds of moral judgment similar to distinguishing between hydrogen and helium on the basis of their atomic number. Implications of this natural kinds approach for assumptions about the universality and innateness of moral judgment have been discussed elsewhere and would surpass the scope of this chapter (Mikhail 2011; Waldmann et al. 2012).

There is also a rich debate on the limited plausibility of the natural kinds concept within the human sciences in general, given the complex interaction between researcher and experimental subject in this domain (Gergen 2001; Hacking 1999). New evidence shows that even basic visual processes such as those underlying the Müller-Lyer illusion (that a line with two arrowheads pointing outwards looks shorter than a line of the same length with arrowheads pointing inwards) are culturally diverse and apparently mediated through learning (Henrich et al. 2010). In the related field of psychiatry that employs many psychological concepts like "attention" or "inhibition" it is widely conceded that no natural essences have been discovered so far despite strong efforts within the biomedical sciences, particularly genetics and neuroimaging (Kendler et al. 2011). Regardless of rather principal considerations on the possibility of psychological natural kinds, the current state of the art within psychology, cognitive neuroscience, and psychiatry as well as the cognitive diversity of the brain identified in fMRI meta-analyses described above make it appear very unlikely that even if such kinds existed, the currently available research methods are sufficient for discovering them.

Conclusion and Future Directions

While many inferences in the empirical sciences, in contrast to philosophical or mathematical logics, are rather inferences to the best explanation than definitive proofs, the previous critical discussion of several steps in the experimental (neuro-) philosophy cycle demonstrates that relating the data back to the original psychological and philosophical puzzles is subject to several views and decisions regarding the psychological constructs, hypotheses, procedures and methods, the analysis, and, eventually, the interpretation. Some of these views and decisions, for example, which model of moral cognition is most compatible with the available findings, can

be tested in further experimentation or through additional and more sophisticated analyses, but some of them, for example, how the constructs of emotion and reason should be understood, what the right method is for establishing their presence in a representative group of experimental subjects, or which statistical test provides the most reliable result, depend on conceptual aspects and convention within a scientific community.

While philosophy, just like any discipline, has to consider empirical findings inasmuch as it makes statements related to empirical subjects, empirical research, by contrast, presupposes theoretical stances on issues like the meaning of concepts which do not exclusively belong to the domain of philosophers, but for whose investigation philosophy provides helpful methods. This point is akin to the general account of the theory-ladenness of observation traditionally established within the philosophy of science (Duhem 1906; Kuhn 1962). However, it certainly deserves further research and discussion in which respect considerations regarding natural kinds differ between natural sciences in the narrow sense, like physics and chemistry, and the often interdisciplinary endeavors of human sciences and philosophy investigating multi-faceted subjects like consciousness, free will, or moral cognition.

Leaving these general issues aside, there is certainly much more to learn about the way people make moral judgments and engage, or fail to engage, in moral action. Whether or not this has implications for moral philosophy was not an issue in this chapter, but has been discussed controversially and extensively elsewhere (Berker 2009; Greene and Cohen 2004; Greene 2008; Kahane 2013; Kauppinen, this section; Rini, this section; Singer 2005). As the field of moral cognition continues to develop, there will certainly be much more discussion on this question. The studies by Greene and colleagues have certainly been inspiring for many neuroscientists, psychologists, philosophers, and other scholars alike, which is reflected in their citational success (see Fig. 12.1). The experimenters conceded that their approach was preliminary, which some might have neglected when relating their findings back to the original psychological and philosophical questions (see Fig. 12.2). Reaching agreement about the operationalization of moral judgments characteristic of important moral theories would help to integrate the findings of different studies with each other. Testing for differences and similarities between different groups of experts, students, and lay people might help as well, particularly when speculating about the way such individuals make their decisions; the author tried this for the case of legal experts such as lawyers and judges making moral and legal judgments (Schleim et al. 2011).

The recent success of and interest in experimental philosophy (Alexander 2012; Knobe and Nichols 2008; *Philosophical Psychology* Special Issue 2010 Vol. 23 No. 3 & 4) or "empirical neurophilosophy" (Northoff 2013), of which the studies by Greene and colleagues might actually be the most famous examples, is accompanied by a surge in critical methodological and theoretical publications questioning common ways of experimentation both within psychology and cognitive neuroscience (*Perspectives on Psychological Science* Special Issues Vol. 4 No. 3; 2010 Vol. 5 No. 6; 2012 Vol. 7 No. 6). Particularly with regard to fMRI, probably the most

successful method within human cognitive neuroscience throughout the last two decades (Friston 2009; Logothetis and Wandell 2004), the localizational where-question might not be as informative psychologically as often thought (Anderson 2010; Pessoa 2008; Poldrack 2006; Schleim and Roiser 2009). New methods yet to be developed will most likely provide better answers to what- and how-questions in the future in order to understand the correlations between brain signals and psychological constructs better, possibly allowing a better mapping between cognitive and brain ontology. For the time being, a critical philosophy of experimentation seems thus necessary in addition to experimental (neuro-) philosophy (Woolfolk 2013).

The initial statement by Helmuth that moral dilemmas provoking paradoxical reactions mean "job security" for philosophers accompanying the first study by Greene and colleagues suggests that once empirical researchers find a reasonable scientific explanation for people's – including philosophers' – moral judgments and views, philosophers might actually lose their jobs. At least in terms of philosophical inquiry, this chapter demonstrated that the experimental approach toward philosophically significant issues, by contrast, offers many new opportunities for scholars of various disciplines, including philosophers.

Neuroscience, Free Will, and Responsibility: The Current State of Play

Abstract

A number of psychologists and neuroscientists have argued that experimental findings about the psychological basis of human behavior demonstrate that we lack free will, or that it is limited in ways we do not realize. In this chapter, I survey some of the main claims in this literature, with an eye to situating the contributions to come. I examine Benjamin Libet's work on the timing of awareness of action initiation, Daniel Wegner's claim that acting and thinking that one is acting dissociate, and related experimental work, and suggest that the threat to free will is smaller than has often been thought. I then turn to the question whether the brain is deterministic, and situate that question within philosophical debates. From global threats to free will, I move to local threats: the claim that the situationist literature in psychology shows that we lack free will under some circumstances. Finally, I examine recent developments in experimental philosophy, which aim to reveal ordinary people's views on free will.

Introduction

Free will, and the closely related topic of moral responsibility, attracts more attention from outside philosophy than just about any other philosophical topic. In important part, this is due to the intrinsic significance of the topic: On many views, free will is required for moral and criminal responsibility, and therefore for the justification of large parts of the legal system (▶ Chap. 81, “Neurolaw: Introduction”). Perhaps for this reason, scientists from a variety of disciplines have found the topic irresistible, from physicists to evolutionary biologists (see, for instance, Suarez and Adams 2013). If free will exists, it is instantiated in human behavior, and the brain plays a central role in human behavior. For that reason, neuroscientists have been especially attracted to the question; correlatively, free will has become an important topic in neuroethics too. I will briefly discuss neuroscientific and, more broadly, cognitive scientific challenges to free will under the headings of *consciousness*, *determinism* and *situationism*, prior to a final discussion of the recent literature in *experimental philosophy* on free will.

Consciousness

One of the most famous experiments in all of neuroscience concerns free will. In ground-breaking work, Benjamin Libet and colleagues (1983) produced evidence that a brain event associated with voluntary movement, the *readiness potential*, begins to occur prior to subjects’ being aware that they have decided to act. This experiment has widely been interpreted as showing that people lack free will. People who advance this argument claim, roughly, that free will requires that we initiate our actions consciously, but if Libet is right we are not conscious of when we initiate action; rather, *first* we initiate action and only *subsequently* do we come to be aware of this fact. Our impression that we consciously initiated the action is an illusion, a confabulation in the jargon of neuropsychology.

We could buttress this argument with related work, both from neuroscience and from psychology. Consider, for instance, Soon et al. (2008): They found that patterns of activation in parietal and prefrontal cortex predicted which of two options subjects chose 7 whole seconds prior to the choice (the gap Libet found between readiness potential and awareness, by contrast, was less than half a second), or Daniel Wegner’s (2002) important work showing a double dissociation between thinking that one is acting and actually acting: Subjects sometimes think they have acted when they have not, and sometimes think they have not acted when they have. This last finding seems to show that our consciousness of our actions is an unreliable guide to the reality. Like Libet, Wegner interprets these results as showing that the conscious self actually plays a relatively small role in behavior: Rather, unconscious mechanisms do the actual work.

As Bayne and Pacherie, in their contribution, and Mele, in his, point out in this volume, this experimental work has been subjected to criticism which highlights

significant methodological problems. Mele (2009) in particular has been a very powerful and persuasive critic of Libet, and of more recent work building on his results. Readers interested in the methodological problems with this research will find details in those contributions. Here I want to focus on some philosophical questions that have not received the same degree of attention. We would do well to question the assumptions made by Libet, Wegner, and others who advance this argument against free will.

In particular, we should focus attention on the claim that if we initiate our actions unconsciously, we do not do so freely. Why think this is true? There is indeed evidence that consciousness is important to the ordinary conception of free will. In recent work, combining empirical data with philosophical analysis, for instance, Stillman et al. (2011) find "that people carefully considered what they should do before they engaged in actions they later regarded as good examples of free will" (391). But notice that the role for consciousness people apparently value is not the role that the scientists just mentioned claim it cannot play: Consciousness of *initiation* is quite different from conscious *deliberation*. Nothing in the empirical work mentioned threatens our belief that we act freely only when we act after careful deliberation (for more discussion, and argument that this kind of freedom can indeed be threatened by work in cognitive science, see Caruso 2012 and for a response see Levy 2014).

Determinism

Neuroscientists have also argued that the deterministic nature of brain processes rules out free will. The argument runs roughly as follows:

1. Free will requires that our actions be undetermined.
2. Neuroscience shows that the brain, which is the cause of our actions, is a deterministic causal machine.
3. Therefore, we lack free will.

As Mark Balaguer shows in his contribution to this volume, however, it is an open question whether the brain is indeed a deterministic system. It is compatible with what we know about both the brain and about physics that some or many brain processes are indeterministic: Certainly, neuroscientists cannot predict with high degrees of accuracy whether a particular neuron will fire or not (see Peter Tse 2013 for an argument that the brain is indeterministic and that therefore we possess free will).

Most philosophers do not think that the argument presented above advances the debate over free will in any useful way. That is because premise 1 of the argument begs the question against the majority view in philosophy regarding free will. *Compatibilists* deny that free will requires that our actions be undetermined. Free actions must not be coerced, compelled, or manipulated actions, they claim, but (deterministic) causation is none of these things. Indeed, some compatibilists have suggested that far from being a threat to freedom, deterministic causation is actually required for free will. A more common view is

that indeterminism does not contribute in any way to free will; it simply makes our actions subject to potentially responsibility-undermining luck (see Levy 2011 for discussion, and see Balaguer, this volume, for dissent). We will return to the issue of determinism shortly.

Situationism

Threats to free will from the sciences of the mind are not, as we have already seen, the exclusive province of neuroscience. A quite different set of experimental results seemed to many to represent a threat to free will: experiments showing that our actions can be significantly affected by features of the environment of which we are not aware, or of whose influence we are not aware. This is akin to the threat from lack of consciousness, but it is distinct: There is no special reason to think that agents are unaware of initiating their actions in these experiments, but there is good reason to think that they are unaware of the influence features of the situation have over them.

Much of this data comes from work on behavioral priming (now quite controversial in psychology, because of some high-profile failures to replicate well-known results). Consider for instance Williams and Bargh (2008). They found that subjects who held a warm drink judged another person as having a "warmer" personality than subjects who held a cold drink, and subjects holding a warm drink were more likely to choose a gift for a friend (rather than themselves) than subjects holding a cool drink (Williams and Bargh 2008). Subjects were aware of a stimulus – the temperature of the cup – but unaware of how it influenced their judgments.

This may seem like a prima facie threat to free will: People's willingness to give a gift to someone (and, as Amaya and Doris sketch in their contribution, to help another in need) is influenced by apparently irrelevant aspects of circumstances. We do not think that whether we act badly or well ought to be settled by these insignificant factors. Prima facie, the role these factors play seems to undermine our free will. Amaya and Doris argue that we should understand moral responsibility not as picking out a single monolithic concept but instead a family of related notions, and that some of these are applicable to agents in the circumstances of these experiments. If we understand free will (as most, though not all, philosophers do) as a power the exercise of which sometimes makes us morally responsible, we will find that the situationist data is no threat to free will after all.

I want to suggest a different but related reason why we might think that this data is not a special threat to free will: Though they certainly play a role in how we act, situational factors like these do not cause us to act contrary to our own values. The person who stops and helps the passer-by, but would have hurried on had they been under time pressure is neither a very decent nor a very bad person, I suggest: Rather, they are someone who genuinely has it in them to act well or badly. Either action is actually compatible with their values. Had they been really decent, the time pressure would not have been sufficient to make them pass by (only clearly excusing conditions would have done that), and had they been really bad, they would not have

helped under any circumstances. In some of the most famous experiments involving helping and harming behavior, such as Milgram's experiment involving the application of a shock to other people, most subjects went – shockingly – far. But some did not: Some resisted the situational pressure. Of course, this defense of free will against situationism concedes that freedom is subject to luck. Some people believe that luck is an independent threat to free will (I am one of them). My point is not that we can show that we are free despite the challenge: rather, it is that if there is a challenge here, it is not from social psychology at all.

Experimental Philosophy

Experimental philosophy is a relatively new movement that combines philosophical analysis with careful experimentation (▶ Chap. 12, "The Half-Life of the Moral Dilemma Task: A Case Study in Experimental (Neuro-) Philosophy"). Though experimental philosophers use a variety of methods and put them to a variety of purposes, one of the primary aims of the movement has been to probe the *intuitions* – roughly, the way things seem to be – of ordinary people. Analytic philosophy often treats intuitions as data (if someone in a particular thought experiment seems to lack knowledge, for instance, that is a good reason to think that someone in those circumstances would actually lack knowledge). It is often important to know whether one's own intuitions are idiosyncratic, or on the contrary widely shared. For that reason, experimental philosophers use carefully designed vignettes to see what factors influence the intuitions of ordinary people.

Under the heading of "determinism" above, I mentioned the compatibilist response to the argument that we lack freedom because the brain is (allegedly) a deterministic causal system. Some people have responded that compatibilism is so bizarre only a philosopher would believe it. Ordinary people, they claim, would need to be argued into accepting such a claim. Experimental philosophers have hotly debated whether compatibilism is highly unintuitive, or whether instead it strikes ordinary people as plausible. Of course, they do not ask ordinary people about "compatibilism." Rather they have given their subjects vignettes, describing the behavior of agents in worlds that are stipulated to be deterministic. They have then asked the subjects whether the agents are morally responsible for their actions (on the assumption, mentioned above, that if an agent is directly morally responsible for an action, the action was performed freely).

One fairly robust finding in the experimental literature is that ordinary people's attitudes depend in part upon how questions about free will are asked. In response to questions such as *if determinism is true, are people responsible for their actions*, a majority of ordinary people say *no*, just as the neuroscientists might have predicted. But when the question posed is more concrete in its form, asking whether a particular person is responsible for a particular crime in a determinist universe, a majority say *yes* (Nichols and Knobe 2007). It remains extremely controversial how we ought to interpret these findings. Nichols and Knobe suggest that the emotions aroused by contemplating morally bad actions cause

people to make a mistake: The emotion interferes with the application of their incompatibilist commitments. Murray and Nahmias (forthcoming) by contrast, think that the incompatibilist responses are actually the result of a confusion between *determinism* – which is a claim about causation – and *bypassing* of psychological capacities. They suggest that if we do not take care to avoid it, people will assume that a description of determinism entails that people's capacities for deliberation and choice are bypassed. That is, people misread the description of determinism as entailing that people will act as they are determined; *however, they decide to act* (rather than as entailing that people are determined to decide in one way rather than another). If we ensure that this confusion is avoided, Murray and Nahmias claim we reveal that most ordinary people are, after all, compatibilists.

The experimental philosophy movement is highly controversial in philosophy: The standard response from more traditional philosophers is to argue that what ordinary people think on first exposure to philosophical issues just is not relevant to what we ought to think once we have thought through the issues carefully. In his contribution to the volume, Tamler Sommers articulates a different worry: that the experimental philosophers are not probing the right intuitions. They are asking whether compatibilism seems right or not, when what they should be doing is asking whether ordinary people accept common (but controversial) *arguments* for compatibilism and incompatibilism. Sommers' point is that the philosophers involved in the free will debate never argue as follows:

1. It seems to me that if determinism is true, we lack free will.
2. Therefore, if determinism is true, we lack free will.

Rather, they present arguments for the incompatibility of free will and determinism. For instance, they argue:

1. If determinism is true, then what we do is the inevitable result of the laws of nature and the physical facts that pertain before we are born.
2. But we lack any kind of power over the laws of nature and the physical facts that pertain before we are born.
3. Therefore, we lack any power over what we do.

(Of course, compatibilists have arguments of their own, and rebuttals to incompatibilist's arguments). Sommers thinks we ought to see how ordinary people respond to these arguments, not how they respond to the simplistic "argument" that preceded it.

In response to Sommers, we might suggest that the more sophisticated arguments, like the one I have just given an extremely simplified version of, are attempts by incompatibilists to systematize and explain their pretheoretical intuition, which really is along the lines of premise 1 of the simplistic argument. If that is right, some case can be constructed for thinking that the intuitions of ordinary people with regard to the simplistic arguments are *also* worth probing. Sommers is certainly right in suggesting that that is not *all* experimental philosophers of free will should be doing. As he concedes, they are beginning to probe intuitions with regard to arguments, as well as continuing the kind of work he regards as fruitless.

Conclusion

The issues canvassed in the contributions to this section, and surveyed in this introduction, remain highly controversial. They are also extremely exciting. They perfectly illustrate the scope and the importance of neuroethics: They are issues that are directly relevant to important human concerns (are we responsible for our actions? Is criminal punishment justified? Ought we to feel pride and shame for what we do and what we are?) and require for their proper assessment both neuroscientific expertise and philosophical sophistication. The papers here represent current thinking by some of the most important contributors to their assessment. They should serve as a stimulus to further research on this significant neuroethical topic.

Abstract

There are three projects within the cognitive science of agency and consciousness that are of particular interest to neuroethics: the *descriptive project*, the *genetic project*, and the *substantive project*. The descriptive project is concerned with characterizing our everyday experience of, and beliefs about, agency. What is the folk view of agency? The aim of the genetic project is to give an account of the psychological mechanisms involved in constructing our experience of, and beliefs about, agency. How is the folk view of agency to be explained? The substantive project is concerned with determining the degree to which our experiences of, and beliefs about, agency are correct and to what degree they

might need to be revised in light of findings from the cognitive sciences. Is the folk view of agency basically correct or does it need to be modified in fundamental ways (as "will skeptics" argue)? This entry provides an overview of recent research relating to all three projects.

Introduction: Three Projects

It is possible to distinguish three distinct, but related, projects in the burgeoning literature on the relationship between agency and consciousness: the *descriptive* project, the *genetic* project, and the *substantive* project. The descriptive project is concerned with charting the contours of what, following Sellars (1962), can be described as the manifest image of human agency. How do we experience our own agency? What is the content of our intuitive, prescientific conception of human agency? The aim of the genetic project is to give an account of the psychological mechanisms involved in the construction of the manifest image of human agency. Why do we have the pre-theoretical conception of agency that we do? The focus of the substantive project is that of determining the degree to which the manifest image of agency is correct. To what extent might the folk conception of agency need to be revised in light of what we have learnt from the cognitive sciences?

Although these projects are formally distinct, there are many important connections between them. Most obviously, tackling the genetic project presupposes that one has made a certain degree of progress with the descriptive project, for until one has an account (if only partial) of the content of the manifest image of agency one won't be in a position to know quite what it is that the genetic project is meant to explain. There are also important points of contact between the genetic project and the substantive project, as we shall see in due course.

The Descriptive Project

The manifest image of agency comprises two kinds of states: agentive *experiences* and agentive *beliefs* (Bayne and Pacherie 2007). Agentive experiences involve the awareness of agency as such. Although some agentive experiences concern the agency of others, we will focus here – as the literature does – on agentive experiences that concern one's own agency (Horgan et al. 2003; Bayne 2008; Pacherie 2008; Wakefield and Dreyfus 1991). The literature contains a great variety of terminology here, with authors referring to experiences of deliberation, experiences of decision-making, experiences of intentionality, experiences of freedom, experiences of mental causation, the awareness of movement, the awareness of intentions to act, the sense of control, the sense of effort, and the sense of agency (among many others).

It is possible to impose some much-needed structure on this discussion by distinguishing two kinds of elements associated with agentive experience: those that are associated with *all* agentive experiences ("core elements") and those

that are associated with only *some* agentive experiences ("non-core elements") (Bayne 2010). One core element of agentive awareness is the sense of oneself as acting. Arguably, this experience cannot exist independently of any experience of what it is one is doing – as a feeling simply "floating in the air" so to speak – but must be accompanied by a sense of *what* it is one is doing, whether that be moving one's body in a certain way (e.g., moving a finger), performing an action of particular kind (e.g., pressing a key), or trying to realize a certain goal (e.g., starting a new paragraph). Having an agentive experience does not require one to identify the action the experience is about at a particular level of specification, but it does demand that the action be specified in some way, however vague. And if that is right, then agentive experience includes two core elements: a sense of agency (i.e., an awareness of oneself as acting) and some specification of the action the sense of agency is directed towards.

What about the non-core elements of agentive experience? Among the various kinds of experiential states associated with agency are experiences of effort, experiences of deliberation, experiences of decision-making, and experiences of freedom. These experiences do not appear to characterize all forms of agency – for example, spontaneously and unreflectively cleaning one's glasses or brushing the hair from one's eyes might not be accompanied by any sense of effort, deliberation, decision-making, or freedom – but they do seem to accompany some of our actions. However, giving a precise characterization of the content of these agentive experiences has proven to be very challenging. For example, although many theorists would agree that there is a sense in which we experience ourselves as free, there is little agreement as to what exactly this sense of freedom involves (Nahmias et al. 2004).

Let us turn now to the other component of the manifest image of agency: agentive belief. We take this label to include all our pre-theoretical (or "folk") beliefs about agency, whether they are held explicitly or whether they are merely implicit in our intuitive responses to situations. Examples of such beliefs might include the belief that we possess free will, that consciousness plays an important role in the control of intentional actions, that deliberation typically improves the quality of decision-making, and so on. However, these characterizations of the folk conception of agency are fairly rough and ready, and it would be nice to have a more precise analysis of what the folk conception of agency involves. A great deal of recent work that has been conducted under the "experimental philosophy" label has attempted to meet this need (see Sommers 2010 for a review). Two issues in particular have been the focus of recent discussion: (1) What is the folk conception of free will and (2) What is the folk conception of intentional agency?

One of the central debates in the philosophy of action is that between compatibilists and incompatibilists. Compatibilists hold that free will and determinism are compatible with each other, whereas incompatibilists hold that they are incompatible with each other. The question that concerns us here is not how free will *should* be analyzed (whatever precisely that might mean) but what conception of free will the folk have. Are the folk compatibilists or incompatibilists?

Attempts to answer this question paint a rather mixed picture (Nichols 2011). Eddy Nahmias and his colleagues have argued that the folk have a predominantly

compatibilist conception of free will (Nahmias et al. 2005; Turner and Nahmias 2006). They presented undergraduates with vignettes outlining a world in which human agency (along with everything else) was perfectly predictable and asked them whether free will was possible in such a world. They found that 76 % of their subjects claimed that free will was possible in such a world, suggesting that the folk are "natural compatibilists."

However, other studies have suggested that the folk have a predominantly incompatibilist conception of free will. In one study, Nichols (2004) presented a group of 4- and 5-year-olds with scenarios involving physical events and moral choices and asked them questions on the model of the following:

Moral choice: "If everything in the world was the same right until she chose to steal, did Mary have to choose to steal?"

Physical event: "If everything in the world was the same right until the time that the water boiled, did the water have to boil?"

Nichols found that the children were more likely to say that the physical events had to happen than they were to say that the moral choice events had to happen, and he concluded that the folk are intuitive incompatibilists.

In work designed to examine the tension between these findings, Nichols and Knobe (2007) explored the idea that folk responses to questions about free will depend on precisely how such questions are framed. Nichols and Knobe described two universes to their subjects, a fully deterministic universe (A) and a universe in which everything except human decisions are deterministically fixed (B). The subjects are first asked which of these two universes most closely resembles our own, with over 90 % of subjects choosing universe B. Subjects are then split into two conditions: an abstract condition and a concrete condition. In the former, subjects are asked whether it is possible for someone in universe A to be fully morally responsible for their actions, with 86 % of the subjects saying "no." But in the concrete condition, 72 % of subjects said that a man in universe A who kills his wife and three children in order to be with his secretary is morally responsible for his actions. In other words, the concreteness (and in particular affective character) of a scenario has an impact on the judgments that subjects make about it.

Just what we should conclude from all of this is, as yet, quite unclear. One possibility is that there is no standard folk conception of free will; instead, significant numbers of folks are compatibilists and significant numbers are incompatibilists; indeed, there is some evidence that individual differences in conceptions of free will covary with personality differences (Feltz and Cokely 2009). Another possibility is that (most) of us don't have a single unified conception of free will but instead have a view of free will that incorporates both compatibilist and incompatibilist elements. Deciding between these (and other) possibilities will no doubt be on the agenda of experimental philosophy for some time to come.

Let us turn now to the folk conception of intentional action. A central question in the analysis of intentional agency is whether foreseen side effects of an action are ever brought about intentionally. Some philosophers have argued that side effects are never brought about intentionally, whereas others have argued that side effects can be brought about intentionally. In an influential series of studies,

Joshua Knobe (2003a, b; see also Malle and Knobe 1997) asked what the folk conception of intentional action is. Knobe discovered that people are much more likely to ascribe intentionality to side effects when those effects are negative (e.g., harming the environment) than when they are positive (e.g., helping the environment). Interestingly, the folk conception of intentional agency is very different from the one which philosophical treatments of intentional agency would have led one to predict.

The Genetic Project

The second of the three projects that we have distinguished is the genetic project: what accounts for the content of the manifest image of agency?

One important question here concerns the relationship between agentive experience and agentive belief. It is plausible to suppose that the content of agentive experience plays a central role in determining the content of agentive belief and that much of what we intuitively believe about agency is grounded in our first-person experiences of agency. On this view, explaining why the manifest image of agency has the content that it does is primarily a matter of explaining why we have the agentive experiences that we do.

This "empiricist" account of the folk conception of agency is not the only option on the table. Another possibility is that certain folk beliefs about agency might be grounded in our moral commitments. For example, Nichols (2004) has suggested that the incompatibilist elements in the folk view of free will might derive from perceived constraints on moral responsibility. The idea is that we reason as follows: we are subject to moral requirements; we could be subject to moral requirements only if we possessed incompatibilist free will; so we possess incompatibilist free will. Note that Nichols does not endorse this argument but merely suggests that it might play a role in explaining the widespread appeal of incompatibilism.

Let us leave these questions to one side and turn to the question of how agentive experience itself might be generated, for it is this issue that has received the lion's share of attention in the recent literature. A number of accounts of agentive experience can be distinguished, but they all have a shared commitment to the idea that the sense of agency is produced when there is a match between cues x and y. What distinguishes these accounts from each other is their conception of (1) the nature of the cues being compared; (2) the nature of the processes involved in the production of the sense of agency; and (3) how closely these processes are related to action production and control processes.

Two positions define the two ends of the spectrum of possibilities: the motor prediction view and the cognitive reconstruction view. On the motor prediction view, the sense of agency is generated by processes dedicated to action control. On the cognitive reconstruction view, the sense of agency is generated by a general-purpose process of retrospective causal inference.

The motor prediction view is inspired by computational theories of motor control. According to these theories, when the motor system generates a motor

command, an efference copy of this command is sent to forward models whose role is to generate predictions about its sensory consequences in advance of actual execution. Error signals arising from the comparison of desired, predicted, and actual states (as estimated from sensory reafferences) are used to make corrections and adjustments. The motor prediction view holds that the signals used for motor control also provide cues to agency (Frith et al. 2000). In particular, it holds (1) that awareness of initiating an action is based on a representation of the predicted consequences of making that action, rather than its actual consequences, and on the congruence between the predicted state and the desired state and (2) that for this experience of agency to continue, the predicted consequences must remain congruent with the sensory reafferences when they become available.

Claim (1) – and therefore the possibility that the sense of agency can emerge in advance of actual sensory effect and be based on premotor processes alone – is supported by evidence that awareness of initiating a movement in healthy subjects occurs between 80 and 200 ms before the movement actually occurs (Libet et al. 1983; Libet 1985; Haggard and Eimer 1999). Evidence for claim (2) – that the sense of agency also depends on the congruence between predictions and sensory reafferences – comes from studies where these reafferences are artificially manipulated by introducing temporal delays and spatial distortions of feedback. These studies demonstrate that the sense of agency is gradually reduced as these discrepancies increase (Fourneret and Jeannerod 1998; Knoblich and Kircher 2004; Sato and Yasuda 2005).

In contrast, the cognitive reconstruction view downplays the contribution of the motor system to the sense of agency and proposes that it is inferred retrospectively from the existence of a match between a prior thought and an observed action. Thus, on Wegner's "theory of apparent mental causation" (Wegner 2002), a general-purpose causal inference process is at play. If an action is consistent with a prior thought of the agent and other potential causes of the action are not present or salient, a sense of agency for the action will be induced.

There is empirical evidence that high-level inferential processes play a role in determining the sense of agency for an action. Studies of Wegner and colleagues have demonstrated that cognitive cues can alter the sense of agency for an action independently of changes in sensorimotor and perceptual cues. For instance, in their "I-Spy" study (Wegner and Wheatley 1999), a participant and a confederate of the experimenter had joint control of a computer mouse that could be moved over any one of a number of pictures on a screen. When participants had been primed with the name of an item on which the mouse landed, they expressed a stronger sense of agency for the action of stopping on that object (when in fact the stop had been forced by the confederate). Further studies also suggest that subliminally priming an outcome just before the outcome is produced can enhance the sense of agency for that outcome (Aarts et al. 2005) and that priming an outcome relatively far in advance of it can augment the sense of agency, but only if the outcome is attached to positive affect (Aarts et al. 2009).

There is now a growing consensus that the motor prediction view and the cognitive reconstruction view are not mutually exclusive but complementary and that intrinsic cues (cues provided by the motor system) and extrinsic cues (such as cognitive primes) both contribute to the sense of agency (Pacherie 2008; Sato 2009; Synofzik et al. 2008; Moore et al. 2009; Moore and Fletcher 2012). Researchers are now trying to develop integrative frameworks in order to get a better understanding of how all these agency cues interact.

One way to try to combine the motor prediction view with the cognitive reconstruction view is to appeal to the distinction between pre-reflective agentive experiences and reflective agentive beliefs or judgments (Bayne and Pacherie 2007; Gallagher 2007; Haggard and Tsakiris 2009) and to argue that while motor processes contribute mainly to feelings of agency, interpretive processes contribute mainly to judgments of agency. This conceptual distinction is echoed methodologically in the ways agency is measured in experimental studies. While some studies (Farrer et al. 2003; Metcalfe and Greene 2007; Sato and Yasuda 2005) investigate agency by asking participants to explicitly judge whether they caused a particular sensory event, other studies use implicit agency measures such as intentional binding and sensory suppression. Intentional binding is a phenomenon, first reported by Haggard and his colleagues (2002), whereby an action and its external sensory consequences are compressed together in subjective time. As intentional binding occurs only for voluntary actions (Tsakiris and Haggard 2003) and is furthermore modulated by the statistical relation between events (Moore and Haggard 2008), it is considered to provide an implicit measure of agency. Sensory attenuation of self-produced action effects has also been used as an implicit measure of agency. When the internally generated motor predictions about the sensory consequences of one's ongoing actions and their actual sensory consequences are congruent, the sensory percept is attenuated, thereby enabling a differentiation between self-generated and externally generated sensory events (Blakemore et al. 2002; Cullen 2004). However, recent studies showing that prior authorship beliefs can modulate both sensory attenuation and intentional binding (Desantis et al. 2011, 2012) suggest that drawing a sharp distinction between feelings of agency supported by motor processes and judgments of agency supported by interpretive processes may be oversimplistic.

A promising approach is to appeal to a Bayesian integrative framework involving a hierarchy of prediction and model building. Thus, Moore and Fletcher (2012) propose that the sense of agency is determined by a Bayesian process of cue integration, where the predictions generated at higher levels of the hierarchy provide the priors for the lower levels, i.e., constrain the interpretation of cues available at lower levels. In this model, cue integration is itself the product of both the strength of the priors and the weights attached to the available cues as a function of their reliability. When priors are weak – as, for example, when one is quite unsure what the effects of pressing a button will be – one may still have a strong sense of agency for the ensuing consequence, provided that perceptual reafferences carrying information about it are very reliable. Conversely, if my

priors are very robust, I may have a strong sense that I produced a certain effect in the world, even though the feedback I get is weak or ambiguous. When both priors and reafferent cues are weak, my sense of agency may be correspondingly weakened. While this Bayesian approach does not allow for a sharp distinction between agentive experiences and agentive judgments, it can accommodate the idea that high-level priors exert more influence on agentive judgments than on agentive experiences.

The Substantive Project

We turn now to the third of three projects that we outlined in the introduction: the substantive project. Briefly put, the aim of the substantive project is to determine the degree to which the manifest image of agency is correct. How accurate are our experiences of and beliefs about agency? The substantive project has dominated discussions of the relationship between agency and consciousness over the last two or so decades. At the center of these discussions is a position that has been dubbed *will skepticism*. Will skeptics argue that important elements of the manifest image of agency are at odds with the scientific image of agency and as such should be rejected or at least revised.

The most popular form of argument for will skepticism attempts to put pressure on the folk conception of agency by trying to show that some of its commitments are false. For example, arguments for will skepticism that appeal to Libet's (1985) influential studies of the readiness potential claim that these studies are at odds with the folk commitment to the idea that freely willed actions are initiated by an act of conscious volition.

These arguments share the following "two-pronged" structure. The first prong involves the claim that the folk conception of agency is committed to ascribing a certain feature ("feature X") to human agency. The second prong involves a claim to the effect that human agency does not in fact possess feature X. Cognitive science is relevant to the evaluation of each of these two prongs. Most obviously, it is relevant to the evaluation of the second prong, for the claim that human action lacks certain features is subject to the tribunal of empirical inquiry. But cognitive science is also relevant to the evaluation of the first prong, for the question of what precisely the folk conception of agency is committed to is a matter of the descriptive project, and that – as we have seen – falls within the domain of cognitive science.

The argument for will skepticism that appeals to Libet's experiments regarding free will and the readiness potential (Libet 1985; Libet et al. 1983) is one of the most the most widely discussed in the current literature (see, e.g., Banks and Pockett 2007; Mele 2009; Nahmias 2013; Sinnott-Armstrong and Nadel 2010). In these experiments, subjects were asked to flex their wrist at will and to note when they felt the urge to move by observing the position of a rapidly rotating dot on a special clock. While subjects were both acting and monitoring their urges (intentions, decisions) to act, Libet used an EEG to record the activity of

prefrontal motor areas. On average, participants reported the conscious intention to act, what Libet called the W judgment, about 200 ms before the onset of muscle activity. By contrast, the EEG revealed that preparatory brain activity, termed by Libet the type II readiness potential (RP), preceded action onset by about 550 ms. In other words, their brain started preparing the action at least 350 ms before the participants became aware of the intention to act. In fact, for reasons that we need not explore here, Libet claimed that this gap was likely to be closer to 400 ms in length.

As a number of commentators have pointed out, Libet's paradigm is subject to a number of methodological problems (see, e.g., the commentaries on Libet 1985). To take just one example of these problems, Libet's paradigm requires subjects to divide their attention between the position of dot on the clockface and their own agency. The demand to divide one's attention between two perceptual streams in this way is a notorious source of error in temporal-order judgments. Despite these difficulties, Libet's basic findings have been replicated by a number of laboratories using studies that are free of these methodological difficulties.

Although there is some variability between studies, the claim that "Libet actions" – that is, simple and (relatively) spontaneous motor actions – involve an RP whose onset precedes the time of the subjects' W judgment by about 400 ms or so is largely undisputed. What is in dispute are the implications of these results for questions concerning free will.

Libet denied that his results establish free will skepticism, for he argued that the gap of 150 ms between the agent's conscious decision and the onset of the action allowed for a kind of free will in the form of conscious veto. However, many theorists have seen in Libet's work the death knell of free will. In their review of his work, Banks and Pockett (2007, p. 658) describe Libet's experiments as providing "the first direct neurophysiological evidence in support of [the idea that perceived freedom of action is an illusion]."

Unfortunately, few skeptics have said exactly how Libet's data are supposed to undermine free will. Here is one way in which Libet's data might be thought to put pressure on free will (Bayne 2011):

1. The actions studied in the Libet paradigm are not initiated by conscious decisions but are instead initiated by the RP.
2. In order to exemplify free will, an action must be initiated by a conscious decision.
3. So, the actions studied in the Libet paradigm are not freely willed. (From [1] and [2]).
4. Actions studied in the Libet paradigm are central exemplars of free will (as intuitively understood), and so if these actions are not freely willed, then no (or at least very few) actions are freely willed.
5. So no human actions are freely willed. (From [3] and [4]).

We will refer to this as *the skeptical argument*. The skeptical argument is valid, so if it is to be resisted, we need to reject one (or more) of its premises. Let us begin by considering (4).

The Scope of Free Will

Are the actions that form the focus of the skeptical argument – “Libet-actions” – paradigm examples of our intuitive notion of free will? Libet himself had no doubts about the answer to this question – he took himself to have studied an “incontrovertible and ideal example of a fully endogenous and ‘freely voluntary’ act” (Libet et al. 1983, p. 640) – but not everyone shares this view. Adina Roskies, for example, claims that Libet-actions are at best “degenerate” examples of free will and suggests that we ought to focus on actions that are grounded in our reasons and motivations if we are interested in “how awareness and action are related insofar as they bear on freedom and responsibility” (2010b, p. 19).

To make progress here we need a taxonomy of action types. One useful distinction is between *automatic* actions and *willed* actions. Automatic actions flow directly from the agent’s standing intentions and prepotent action routines. Many of our everyday actions – washing the dishes, answering the telephone, and reaching for a door handle – are automatic. Our awareness of various features of our environment together with overlearned action schemas conspires to trigger the appropriate actions with only the minimal participation of conscious deliberation or decision on the part of the agent. Willed actions, by contrast, require the intervention of executive processes. Some willed actions – what we call “deliberative actions” – involve only decision. Consider the experience of finding oneself in a restaurant confronted by a number of equally attractive – or, as the case may be, unattractive – options on the menu. One needs to make a choice, but it does not matter what one orders. Other willed actions – what we call “deliberation actions” – involve both decision and deliberation. Consider Sartre’s case of the young man who must choose whether to look after his aged mother or join the resistance. Here, the function of decision-making is not to select from amongst a range of options between which one is relatively indifferent (as is the case in contexts of disinterested actions) but to draw on one’s reasons in making a good decision.

Are Libet-actions automatic or willed? Although they are embedded in a wider agentive context – a context that includes a conscious decision to produce an action of a certain type within a certain temporal window – Libet-actions are not plausibly regarded as automatic. Unlike standard examples of automatic actions, Libet actions are not triggered by an external cue. They may not be the “ideal examples” of fully spontaneous agency that Libet took them to be, but Libet-actions do seem to be genuine instances of willed agency nonetheless.

But although Libet-actions involve an act of will, they do not involve deliberation – at least, not immediately prior to the action. They are “disinterested” rather than “deliberative” actions, for the agent has no reason to flex their wrist at one particular time rather than another or to flex it in one way rather than another. Indeed, Libet experiments are explicitly constructed so as to minimize the rational constraints under which the subject acts. We might think of Libet-actions as manifesting the liberty of indifference.

With the foregoing in hand, let us return to the question of whether Libet-actions are paradigms of free will (as we intuitively conceive of it). Are disinterested actions our central exemplars of free will, or does that epithet belong to deliberative actions? Philosophers do not agree on the answer to this question, and the systemic research that would be required in order to settle this dispute has not been carried out. That being said, we suspect that Roskies is right to identify the central or core cases of free will – at least, the kind of free will that is most intimately related to moral agency – with deliberation and rational reflection.

But even though Libet-actions might not be paradigms of free agency, it seems clear that they *do* fall within the scope of our pre-theoretical notion of free will. As such, the free will skeptic is perfectly within his or her rights to claim that if Libet actions – and indeed disinterested actions more generally – are not free, then an important component of our commonsense conception of free will would be threatened. In sum, although (4) is unacceptable as stated, the skeptical argument is not thereby rendered impotent, for the question of whether Libet-actions manifest free will is itself an important one. Libet actions might not qualify as ideal examples of free will, but they do provide the free will skeptic with a legitimate target.

The Initiation of Free Action

Let us turn now to the second premise of the skeptical argument:

> (2) In order to exemplify free will, an action must be initiated by a conscious decision.

We can think of (2) as the "conceptual" step of the skeptical argument, for its plausibility turns chiefly on the contours of our everyday (or "folk") notion of free will.

But is (2) true? In order to engage with this question, we need to consider what it means for an action to be initiated by a conscious decision. According to one view, an action is initiated by a conscious decision only if it has its point of origin in a conscious decision that is itself uncaused. Is this how we should understand (2)?

Certain incompatibilists might think so. More to the point, certain kinds of incompatibilists might argue that the *folk* are implicitly committed to this claim and thus any evidence to suggest that this claim is false would require that our folk conception of free will be modified in some way. However, as we noted in discussing the descriptive project, it is far from clear just what "the folk" conception of free will is. Although the folk can be prompted to give incompatibilists responses in certain contexts, they can also be prompted to give compatibilists responses in others, and thus it remains an open question just how deeply committed the folk are to incompatibilism.

Let us turn to another reading of (2). One might argue that all it is for an action to be initiated by a conscious decision is for that action to have its point of origin in that decision, without also requiring that that decision is itself an uncaused event. Is (2) plausible even on this weaker reading of it?

Note first that the very idea that an action can always be traced back to a *single* point of origin is open to challenge. Rather than thinking of actions as originating with particular discrete events, we might do better to conceive of them as the outcome of multiple events and standing states, no single one of which qualifies as "the" point of origin of the action. Just as the Nile has more than one tributary, so too many of our actions might result from multiple sources.

Secondly, to the extent that free actions can be traced back to a point of origin, it is by no means obvious that this point of origin must always be a conscious decision (Levy 2005). Consider a thoughtless comment that is uttered on the spur of the moment and without forethought. Despite the fact that such an utterance is not consciously initiated, one might think that the notion of free will has some kind of grip in such contexts. But, the objection continues, if that is right, then (2) is too demanding: freely willed actions need not be initiated by conscious decisions.

In response to these points, the advocate of the Libet argument might argue that even if it's not an essential feature of all freely willed actions that they have their point of origin in a conscious decision, it is a feature of the kinds of (supposedly free) actions that *Libet* studied. Unlike those actions that we experience as automatic, Libet-actions are accompanied by the "phenomenology of conscious initiation": one experiences oneself as deciding to act here-and-now. And, the will skeptic might continue, if the neural data demonstrate that the action has been initiated before the agent is aware of their decision, then this sense of origination is illusory.

Some authors would take issue with this characterization of the agentive experience that accompanies Libet-actions. For example, Terry Horgan (2010) acknowledges that one would experience oneself as beginning to actively undertake an action at some specific moment in time, but he denies that this phenomenology would involve any sense that one's behavior is caused by one's mental states. Instead, he suggests, one would experience oneself as "authoring" the behavior. Horgan's comments raise deep and important issues, but we lack the space to engage with them here. Instead, we will turn to the first premise of the Libet argument and the question of whether Libet-actions really are initiated by the readiness potential rather than the agent's conscious decision.

Conscious Decisions and the Readiness Potential

The first premise of the skeptical argument is as follows:

> (1) The actions studied in the Libet paradigm are not initiated by conscious decisions but are instead initiated by the RP.

In order to evaluate (1), we need to consider what it is for an event to initiate an action. Let us say that ε initiates α only if there is a robust correlation between ε-type events and α-type events, such that in normal contexts there is a high probability that an ε-type event will be followed by an α-type event. (The notion of origination clearly requires more than this, but it is implausible to suppose that it requires less than this.) So, if the RP initiates the agent's action, then we ought to expect RP events to be "immediately" followed by the appropriate action, unless something unusual happens (such as the person being struck by lightning). Or, to put it the other way around, we should expect that when there is no movement, there is also no RP event. Is this the case?

As several commentators have observed, the back-averaging techniques used to measure RPs do not allow us to answer this question. Because the RP on any one trial is obscured by neural noise, what is presented as "the RP data" is determined by averaging the data collected on a large number of trials. In order to compute this average, the EEG recordings on different trials need to be aligned, and this requires some fixed point – such as the onset of muscle activity or some other observable behavior on the part of the subject – that can be identified across trials. This technique has two main drawbacks. First, as Roskies (2010b) and Trevena and Miller (2002) note, because it involves averaging across a number of trials, certain aspects of the data might be statistical illusions. In other words, features of the relationship between (say) the RP and the W judgment might characterize the averaged data even thought they do not characterize any of the individual trials that contribute to that grouped data. Second, because action onset serves as the needed fixed point for the alignment of EEG recording, any RPs that are not followed by an action simply won't be measured, and so we don't know how robust the correlation between the RP and Libet actions is (Mele 2009).

There are indirect reasons for thinking that the relation between the RP and subsequent action may not be as tight enough for the RP to qualify as the point of origin of the action. Firstly, we know that the nature of the experimental context can significantly affect both the temporal properties and the strength of the RP signal. Subjects who are highly motivated to perform the task produce a large RP, whereas the RP almost disappears in subjects who have lost interest in the task (McCallum 1988; Deecke et al. 1973; see also Rigoni et al. 2011). Secondly, it is possible to make willed responses to stimuli in very much less than 550 ms, which indicates that a type II RP is not "the" point of origin even where it occurs. Thirdly, another neural event – the *lateralized* readiness potential (LRP) – appears to be more strongly coupled to agency than the (generalized) RP is. Whereas the (generalized) RP is symmetrically distributed over both hemispheres, the LRP is restricted to the hemisphere contralateral to the hand that is moved. Haggard and Eimer (1999) found that the LRP was more robustly correlated with the subsequent action than the RP as well as tightly coupled to the W judgments that subjects make. However, a version of the Libet argument in which (1) is replaced with a corresponding claim about the LRP does not possess even the surface plausibility that (1) does. (Note, however, that a recent study by Schlegel et al. (2013) failed to replicate Haggard

and Eimer's finding, and found no within-subject covariation between LRP onset and W judgment, leading them to conclude that neither RP onset nor LRP onset cause W).

In a recent experiment, Schurger and colleagues (2012) used a modified Libet task to circumvent the limitations due to back-averaging techniques. Their aim was to test the proposal that RPs correlate with predecision activity rather than with activity which coincides with, or is subsequent to, the agent's decision (as Libet thought). Schurger and colleagues proceeded by assuming that the decisions of the participants in Libet's experiment can be modelled – as neural decision tasks typically are – in terms of an accumulator-plus-threshold mechanism: decisions are made when relevant evidence accumulated over time reaches a threshold. What is unique to Libet's task is that subjects are explicitly instructed not to base their decision on any specific evidence. Schurger and colleagues propose that the motor system constantly undergoes random fluctuations of RPs and that this random premotor activity is used as a substitute for actual evidence. According to their stochastic decision model, the decision process, given Libet's instructions, amounts to simply shifting premotor activation up closer to the threshold for initiation of the movement and waiting for a random threshold-crossing fluctuation in RP. Time-locking to movement onset ensures that these fluctuations appear in the average as a gradual increase of neuronal activity, when in fact what is measured are simply random fluctuations of RPs that happened to cross a decision threshold.

Thus the two models predict the same premotor activation buildup when a movement is produced, but whereas on Libet's postdecision interpretation of this buildup there should be no premotor activity (and hence no RPs) when no movement is produced, on the predecision interpretation there should be continuous random fluctuations in RPs even when no movement is produced. Schurger and colleagues reasoned that it should be possible to capture these fluctuations by interrupting subjects in a Libet task with a compulsory response cue and sorting trials by their reaction times. On the assumption that the interrupted responses arise from the same decision accumulator as the self-initiated ones, response times should be shorter in trials in which the spontaneous fluctuations of RPs happened to be already close to threshold at the time of the interruption. On the assumption that close to threshold activity reflects spontaneous fluctuations of RPs rather than mounting preparation to move building over the course of the entire trial, slow and fast reaction times should be distributed equally across time within trials. To test these predictions, they devised what they called a *Libetus interruptus* task, where they added random interruptions to trials. They found, as they had predicted, that slow and fast responses to interruptions were distributed equally throughout the time span of the trial.

According to the predecision model, Libet's contention that the neural decision to move happens much before we are aware of an intention or urge to move is unfounded. The neural decision to move isn't made when a RP starts building up, since spontaneous fluctuations of RPs happen all the time, but when a random fluctuation in RP crosses a threshold. The reason we do not experience the urge to move earlier is simply that the decision threshold has not yet been crossed and thus the decision has not yet been made. While Schurger and colleagues take no stand on

the exact temporal relation between the conscious urge to move and the neural decision to move, their results cast serious doubt on Libet's claim that the neural decision to move coincides with the onset of the RP and thus on his further claim that since RP onset precedes the urge to move by 350 ms or more, conscious intentions play no role in the initiation of the movement. If instead the neural decision to move coincides with a much later threshold-crossing event, it remains at least an open possibility that this event coincides with and constitutes the neural basis of a conscious urge to move. In any case, Schurger and colleagues also insist that this threshold-crossing event should not be interpreted as *the* cause of the movement but rather as simply one of the many factors involved in the causation of self-initiated movements.

Taken together, these points suggest that the RP is unlikely to qualify as "the" point of origin of the action. If the RP has a psychological interpretation – and it is far from clear that it does – then we should perhaps think of it as the neural correlate of an "urge" or "inclination" to act, rather than as the neural basis of the decision to act now (Gomes 1999; Mele 2009). The RP may be one of the many tributaries that contribute to an action, but it is not its "origin" in any intuitive sense of that term.

Other Sources of Will Skepticism

In a series of papers and most influentially in his book *The Illusion of Conscious Will*, Daniel Wegner has argued that central components of the folk psychological conception of agency are inaccurate and should be jettisoned. As he puts it, the conscious will "is an illusion." Precisely what Wegner means by describing the conscious will as an illusion is open to some debate (Bayne 2006; Mele 2009; Nahmias 2002), but we take his central claim to be this: agentive experience misrepresents the causal path by means of which one's own actions are generated.

One reason that Wegner gives for thinking that the conscious will "is an illusion" involves the idea that agentive experiences are theoretically mediated. As he puts it, "[Conscious will is an illusion] in the sense that the experience of consciously willing an action is not the direct indication that the conscious thought has caused the action" (Wegner 2002, p. 2). As we have seen, there is very good reason to think that agentive experiences are theoretically mediated, but it is difficult to see why will skepticism should follow from this. Even if the folk are intuitively inclined to think that our access to our own agency is direct and unmediated – and we are far from certain that such a view *is* part of the folk conception of agency – there is little reason to think that such a view is part of the core conception of agency.

Another sense in which one might regard the conscious will as illusory involves the idea that experiences of doing are systematically, or at least frequently, *non-veridical*: experiences of doing misrepresent our agency and the structure of our actions. This seems to be Wegner's main line of argument for will skepticism, and *The Illusion of Conscious Will* contains extensive discussion of cases that are alleged to involve dissociations between the exercise of agency and the phenomenology of agency. Some of these cases appear to demonstrate that we can experience ourselves

as doing something that someone else is doing (and that we are not). Wegner calls such cases *illusions of control*. The I-Spy experiment (discussed earlier) is an example of an illusion of control. Other dissociations involve experiencing someone (or something) else as the agent of what one is doing. Wegner calls such phenomena *illusions of action projection*. Among the most fascinating of the various illusions of action projection that he discusses is facilitated communication, a practice that was introduced as a technique for helping individuals with communication difficulties. Facilitators would rest their hands on the hands of their clients as the client typed a message. Although the facilitators experienced no sense of authorship towards the typed message, there is ample evidence that the content of "facilitated" messages derived from the facilitator rather than the client (Wegner et al. 2003).

How might these dissociations support the case for will skepticism? On one reading of his argument, Wegner is mounting an inductive generalization: since some experiences of conscious will are non-veridical, it is reasonable to infer that most, and perhaps even all, such experiences are. But this argument seems weak, for the fact that experiences of agency *can* be non-veridical shows that the mechanisms responsible for generating such experiences are *fallible* but it does not show that they are *unreliable*. Another way to read the argument from dissociations is as an inference to the best explanation. The argument proceeds as follows: Since the phenomenology of agency plays no direct role in the genesis of action where such experiences are absent, we have good reason to think that it plays no direct role in the genesis of action when such experiences are present. As Wegner himself puts it, "If conscious will is illusory, automatisms are somehow the 'real thing', fundamental mechanisms of mind that are left over once the illusion has been stripped away. Rather than conscious will being the rule and automatism the exception, the opposite may be true" (2002, p. 143).

What does it mean to say that automatisms are the *fundamental* mechanisms of mind? To the extent that automatisms are action-generation procedures that do not involve intentional states of any kind then there may be a tension between automaticity and the experience of conscious will, but Wegner provides little evidence for the view that our actions are usually automatic in this sense of the term. If, on the other hand, automatisms are action-generating procedures that are nonconsciously initiated, then there is ample reason to describe much of what we do as automatic in nature. But on this conception of an automatism there is no conflict between automaticity and the feeling of doing. So there is no argument from automaticity (thus conceived) to the claim that the experience of conscious will is an illusion.

We do not deny that the phenomenology of agency *can* be illusory. Consider, for example, the experience of intentionality. An experience of intentionality will be non-veridical if the action in question is not guided by an intention or if it is guided by an intention other than the one that it seems to have been produced by. The phenomenon of confabulation suggests that at least one if not both of these conditions occur. But I think that there is little reason to assume that either kind of mistake is at all common in everyday life. Confabulation is striking precisely because it is unusual.

In fact, Wegner's own account of the genesis of the experience of doing suggests that such experiences will normally be veridical. According to the matching model, we experience ourselves as doing X when we are aware of our intention to X as being immediately prior to our X-ing and when we are not aware of any rival causes of our X-ing. Now, if we experience ourselves as having an intention to X, then it probably is the case that we do have the intention to X. (After all, it seems reasonably to suppose that introspection is generally reliable. At any rate, Wegner is not in a position to challenge the reliability of introspection, for he himself assumes the reliability of introspection insofar as he takes subjects to be reliable in reporting their experiences of conscious will.) But if one has an intention to X, and if one has in fact X-ed, and if one's intention to X is immediately prior to one's X-ing, then it is highly likely that one's intention to X is involved in bringing about one's X-ing. It would be remarkable if one had an intention to raise one's hand just prior to raising one's hand, but the intention played no causal role in the raising of one's hand. Far from showing that experiences of agency are illusory, Wegner's own model of how such experiences are generated predicts that they will normally be veridical.

Conclusion

Discussions of human agency in the last decades have been dominated by the issue of whether the scientific image of human agency undermines the manifest image of human agency and in particular its commitment to free will. For the most part, cognitive scientists have argued that the folk view of agency is undermined by cognitive science, whereas philosophers have generally denied that there is any such tension, either on the grounds that the scientists in question have misinterpreted the neuroscientific findings or on the grounds that they have assumed a tendentious account of the folk conception of agency.

Although neither camp can claim a decisive victory in this debate, it has prompted theorists to take a closer and more nuanced look at both agentive belief and experience, showing them to be more subtle and less monolithic than previously thought. It is also clear that both elements of the manifest image of agency have complex etiologies and that the sense of agency in particular depends on the integration of multiple cues. Finally, recent research in the neuroscience of decision and action control reveals both the multilevel structure of these processes and the flexibility of their organization.

These advances suggest that we should resist the temptation to think in dichotomous terms and that we may need to replace such questions as whether we have free will, whether we are natural incompatibilists, and whether our sense of agency is veridical with questions that do not lend themselves to yes/no answers. As Roskies (2010a) notes, it is also clear that the time is ripe for philosophers, cognitive scientists, and neuroscientists to engage in more constructive endeavors and use all of the tools at their disposal to advance a positive conception of human agency, one that does justice both to its strengths and to its limitations.

Determinism and Its Relevance to the Free-Will Question

Abstract

This paper begins with an argument for the claim that the compatibilism question (i.e., the question of whether free will is compatible with determinism) is less relevant than it might seem to questions about the metaphysical nature of human decision-making processes. Next, libertarianism (i.e., the view that human beings possess an indeterministic, libertarian sort of free will) is defended against a number of objections, and it is argued that there's a certain subset of our decisions (which can be called *torn* decisions) for which the following is true: If these decisions are appropriately undetermined at the moment of choice, then they are also free in a libertarian sort of way. This is an extremely important

and surprising result; it entails that the question of whether libertarianism is true reduces to the straightforwardly empirical question of whether our torn decisions are in fact undetermined (in the appropriate way) at the moment of choice. Finally, the paper ends by arguing that as of right now, there is no compelling empirical evidence on either side of this question. In other words, the question of whether our torn decisions are appropriately undetermined is an open empirical question. And from this, it follows that the question of whether libertarianism is true is also an open empirical question.

Introduction

I will do two things in this paper. Ultimately, I will discuss how much evidence there is for various kinds of determinism that might be relevant to the question of whether we humans have free will. Before I do that, however, I will discuss the issue of whether the determinism question is even relevant to questions about the kinds of freedom we have.

Is the Determinism Question Relevant to the Free-Will Question?

Let *determinism* (or as I will sometimes call it, *universal determinism*) be the thesis that every event is causally necessitated by prior events together with causal laws. *Prima facie*, this thesis seems to be incompatible with the thesis that human beings have free will. For if it was already causally determined a billion years ago that my life would take the exact course that it's actually taken – that all of my actions and decisions would turn out exactly as they have – then it would seem to follow that I don't have free will. But some philosophers deny this; they endorse *compatibilism*, i.e., the thesis that free will is compatible with determinism. Compatibilists usually try to motivate their view by (a) providing an analysis of the notion of free will and (b) arguing that, given their analysis, it follows that free will is compatible with determinism. For instance, Hume famously argued that free will is compatible with determinism because free will is essentially just *the ability to do what you want*. Hume put his analysis like this (1748, p. 104):

> By liberty, then, we can only mean *a power of acting or not acting according to the determinations of the will*; that is, if we choose to remain at rest, we may; if we choose to move, we also may.

Putting this into contemporary lingo (and altering it somewhat), we arrive at the following definition:

> A person S is *Hume-free* iff S is capable of acting in accordance with his or her choices and of choosing in accordance with his or her desires; i.e., iff it is the case that if he or she chooses to do something, then he or she does it, and if (all things considered) he or she wants to make some choice, then he or she does make that choice.

Hume's argument for compatibilism is based on the following two claims:

(i) Hume-freedom captures the ordinary notion of free will (that is, Hume-freedom *is* free will).

(ii) Hume-freedom is compatible with determinism.

The only controversial claim here is (i). In other words, (ii) is entirely obvious. Hume-freedom requires only that our actions flow out of our decisions and our decisions flow out of our desires, but this could be the case even if all of our desires and decisions and actions are causally determined. To appreciate this, it's sufficient to notice that it could be that (a) it was causally determined by the big bang and the laws of nature that we would all have the desires that we actually do have and (b) our desires causally determine our decisions and our decisions causally determine our actions.

Given this, incompatibilists (i.e., those who think that free will is incompatible with determinism) are forced to reject premise (i) of the Humean argument. And that's exactly what they do; they reject the Humean analysis of free will, and they endorse instead a *libertarian* analysis. There are a few different ways to define libertarian-freedom (or as we can also call it, *L-freedom*), but one way to do this is as follows:

> A person is *libertarian-free* (or *L-free*) if and only if he or she makes at least some decisions that are such that (a) they are both undetermined and appropriately nonrandom and (b) the indeterminacy is relevant to the appropriate nonrandomness in the sense that it *generates* the nonrandomness, or *procures* it, or *enhances* it, or *increases* it, or something along these lines.

A lot needs to be said about what appropriate nonrandomness consists in, but the basic idea is that in order for a decision to count as appropriately nonrandom, the agent in question has to be centrally involved in the decision. Different philosophers might say slightly different things about what exactly this amounts to, but I think most libertarians would say that the most important requirement for appropriate nonrandomness is that the agent in question has to *author and control* the decision; i.e., it has to be *her* decision, and she has to control which option is chosen. (Other requirements for appropriate nonrandomness might include some kind of *rationality* and what Kane (1996) calls *plural* authorship, control, and rationality; but none of this will matter in what follows.)

In any event, the main point here is that incompatibilists disagree with Humean compatibilists about what free will *is*. Both parties can agree that Hume-freedom is compatible with determinism and L-freedom isn't. But they disagree about whether free will is Hume-freedom or L-freedom.

It's also important to note that the Humean analysis of free will isn't the only compatibilist analysis in the literature. Alternative compatibilist analyses (of not just free will, but moral responsibility) have been put forward by a number of different philosophers, e.g., P.F. Strawson (1962); Frankfurt (1971); Watson (1975); Wolf (1990); Fischer (1994); Wallace (1994); Mele (1995); and McKenna (2012), to name just a few. And, of course, each different analysis of free will gives us a different kind of freedom; thus, e.g., we can define *Frankfurt-freedom*, *Watson-freedom*, *Fischer-freedom*; and so on.

So the question of whether free will is compatible with determinism essentially boils down to the question of whether free will is L-freedom or one of these compatibilist kinds of freedom.[1] Now, this might seem pretty straightforward, but the question is notoriously difficult, and there's no consensus on what the right answer is. There are numerous arguments on both sides of the debate – e.g., there's the Frankfurt-case argument for compatibilism, first articulated in Frankfurt (1969); there's the consequence argument for incompatibilism (the locus classicus of this argument is van Inwagen (1975), but see also Ginet (1966) and Wiggins (1973)); there's the manipulation argument for incompatibilism (see, e.g., Pereboom (2001)) – but none of these arguments have proved really compelling, and at the present time, it seems fair to say that, as a community, we just don't know whether free will is compatible with determinism.

Given this, you might think we should conclude that we don't know the answer to the main question of the present section – i.e., that we don't know whether

The determinism question: Is determinism true?

is relevant to

The do-we-have-free-will question: Do humans have free will?

More specifically, you might think we should say that in order to figure out whether the determinism question is relevant to the do-we-have-free-will question, we first need to figure out what free will is. If free will is L-freedom, then the determinism question *is* relevant to the do-we-have-free-will question, and if free will is some compatibilist kind of freedom, then the determinism question *isn't* relevant to the do-we-have-free-will question.

There's a sense in which this is right, but it seems to me that it's also misleading. For there's another way to think about the issues here, and on this other way of conceptualizing things, less turns on the compatibilism debate than the above remarks suggest. In particular, it seems to me that regardless of whether compatibilism is true, we already know right now that the determinism question is highly relevant to an important question about the nature of human freedom. To appreciate this, notice first that the do-we-have-free-will reduces to (or is subsumed by, or some such thing) the following two more fundamental questions:

The what-is-free-will question: What is free will? That is, is it Hume-freedom, or L-freedom, or what?

The which-kinds-of-freedom-do-we-have question: Which kinds of freedom do humans have? That is, do they have L-freedom?; and do they have Hume-freedom?; and do they have Frankfurt-freedom?; and so on. (Actually, to be more precise, we can formulate this question as asking which kinds of "freedom" humans have, since some or all of the kinds of "freedom" we're asking about

[1]You might think that for some of the so-called compatibilist kinds of freedom in the literature, it's actually not obvious that they really are compatible with determinism. If this is right, then if it also turned out that one of these kinds of freedom was free will, then we couldn't settle the compatibilism question by merely determining that free will was the given kind of freedom; we would also need to determine whether the given kind of freedom was compatible with determinism.

here might fail to *be* free will, according to the correct answer to the what-is-free-will question.)

We can think of the latter question here (i.e., the which-kinds-of-freedom-do-we-have question) as the *metaphysical* part of the do-we-have-free-will question – i.e., the part that's actually about the nature of human beings and human decision-making processes. The former question isn't really about *us* at all; it's a *semantic* question.[2] But notice now that the determinism question is obviously relevant to the which-kinds-of-freedom-do-we-have question because it's relevant to the *libertarian question*, i.e., the question of whether humans are L-free. (Actually, one might deny that the determinism question is relevant to the libertarian question; I'll discuss this in the next section, but for now, I will ignore this.) In any event, this is what I had in mind when I said that there's another way to think about the issues here. For if we assume that the determinism question is indeed relevant to the libertarian question, then without even answering the compatibilism question (or the what-is-free-will question), we arrive at the result that the determinism question is relevant to an interesting and important question about the nature of human freedom, namely, the libertarian question, i.e., the question of whether we're L-free.

Now, I suppose you might claim that if it turns out that L-freedom isn't free will (i.e., that L-freedom isn't the referent of the ordinary term "free will"), or if it turns out that L-freedom isn't required for moral responsibility, then the libertarian question is, in fact, *not* interesting or important. But this is just false. The question of whether we possess an indeterministic, libertarian sort of freedom is *intrinsically* interesting and important. In other words, even if L-freedom isn't required for moral responsibility, and even if it isn't the referent of the ordinary term "free will," the question of whether we actually *possess* L-freedom is itself an interesting and important question about the nature of human beings and human decision-making processes. (Of course, there are *some* people who *aren't* interested in the question of whether we're L-free, but so what? – that's true of every question. There are lots of people who aren't interested in whether Alpha Centauri has planets, or what the ultimate laws of physics are, or whether humans are morally responsible for their actions. That doesn't make these questions uninteresting or unimportant.) In any event, since the libertarian question is itself an interesting and important question about the nature of human freedom, it follows that, regardless of whether compatibilism is true, the determinism question is relevant to an interesting and important question about human freedom, namely, the libertarian question, i.e., the question of whether we're L-free.

---

[2]Some people would say that the what-is-free-will question is essentially equivalent to the question, "Which kind(s) of freedom are required for moral responsibility?" But (a) I think it can be argued that the which-kinds-of-freedom-are-required-for-moral-responsibility question is *also* a semantic question (because it's just a subquestion of the what-is-moral-responsibility question), and (b) even if it's not a semantic question, it's pretty clearly not about the metaphysical nature of human decision-making processes.

Is the Determinism Question Relevant to the Libertarian Question?

Libertarianism is often defined as the view that (a) human beings possess L-freedom and (b) L-freedom is free will. But in what follows, I will be concerned with thesis (a) only, and so I will take libertarianism to be the view that humans are L-free, and when I talk about "the libertarian question," I will have in mind the question of whether we are L-free.

Now, *prima facie*, it seems obvious that the determinism question is relevant to the libertarian question. After all, the libertarian question is just the question of whether we're L-free, and L-freedom requires indeterminism, and so it seems obvious that the determinism question is relevant to the libertarian question. But you might question this. You might think we can know by logic alone that we're *not* L-free because the notion of L-freedom is *incoherent*. And if this is right, then the question of whether determinism is true is actually not relevant to the question of whether we're L-free.

The key claim here is obviously that libertarianism is incoherent. This point has been argued by a number of different philosophers – see, e.g., Hobbes (1651), Hume (1748), and Hobart (1934) – but the reasoning is always very similar. One way to formulate the argument here is as follows:

> *Anti-libertarian argument*: Any event that's undetermined is uncaused, and so it *just happens* – i.e., it happens randomly. Thus, if we insert an undetermined event into a decision-making process, we're inserting a *random* event into that process. But given this, it's hard to see how there could be any undetermined events in our decision-making processes that increase (or generate, or enhance, or whatever) appropriate nonrandomness. Appropriate nonrandomness has to do with the agent being in control. How could this be increased by inserting a random event into the process? It seems that it couldn't, and so it seems that libertarianism couldn't be true.

How libertarians respond to this argument is largely determined by the kind of libertarianism they endorse. Broadly speaking, there are three different kinds of libertarian views. First, there are *event-causal* views, which hold that undetermined L-free decisions are *nondeterministically caused* by prior events (I think the best way to fill this view in is to say that these decisions are *probabilistically caused* by prior events, most notably events having to do with the agent's reasons); event-causal views have been developed by, e.g., van Inwagen (1983), Kane (1996), Ekstrom (2000), and Balaguer (2010). Second, there are *noncausal* libertarian views, which hold that L-free choices are completely uncaused (see, e.g., Ginet (1990)). And third, there are *agent-causal* views, which hold that L-free decisions are caused but not by prior events; rather, they're directly caused by *persons* via a special causal relation known as *agent causation*; views of this kind have been endorsed by, e.g., Reid (1788), Chisholm (1964), R. Taylor (1966), C.A. Campbell (1967), Thorp (1980), Rowe (1987), O'Connor (2000), and Clarke (1993).

In this section, I will briefly sketch an event-causal response to the above anti-libertarian argument. Most libertarians who have tried to respond to the anti-libertarian argument have done so by trying to explain how our decisions could be simultaneously undetermined and appropriately nonrandom. But I think

libertarians can motivate a much stronger claim than this. I think they can motivate the following thesis:

> (L) There's an important subset of our decisions (I'll call them *torn decisions*, and I'll characterize them shortly) for which the following is true: If they're undetermined in the right way, then they're also appropriately nonrandom (i.e., we author and control them), and the indeterminacy in question procures the nonrandomness, and so they're L-free.

This is a really strong result; if it's right, what it shows is that the anti-libertarian argument gets things exactly backwards; more precisely, it shows that a certain kind of indeterminism is sufficient for the truth of libertarianism. And, of course, it also shows that, contrary to what the anti-libertarian argument suggests, the determinism question is definitely relevant to the libertarian question.

Before I argue for (L), I first need to say what a torn decision is, and I need to say what the relevant sort of indeterminacy is, i.e., I need to say exactly how a torn decision needs to be undetermined in order to be L-free. Thus, let me start by saying this:

> A *torn decision* is a decision in which the person in question has reasons for multiple options, feels torn as to which option is best, and decides without resolving the conflict, i.e., decides while feeling torn.

I think we make decisions like this several times a day about things like whether to have eggs or cereal for breakfast, and whether to drive or bike to the office, and so on. But we can also make torn decisions in connection with big life-changing decisions; e.g., you might have a good job offer in a bad city, and you might have a deadline that forces you to decide while feeling utterly torn. (Torn decisions are obviously a lot like Kane's self-forming actions, or SFAs. But there are a few differences. Note, in particular, that unlike SFAs, torn decisions are not defined as being undetermined. They're defined in terms of their phenomenology. Thus, we know from experience that we do make torn decisions, and it's an empirical question whether any of these decisions are undetermined in the right way.)

Next, let me define the relevant sort of indeterminacy, i.e., the sort that's needed for an ordinary torn decision to be fully L-free. We can do this as follows:

> A torn decision is *wholly undetermined* at the moment of choice – or, as I'll also say, *TDW-undetermined* – iff the actual, objective moment-of-choice probabilities of the various reasons-based tied-for-best options being chosen match the reasons-based probabilities (or the phenomenological probabilities), so that these moment-of-choice probabilities are all roughly even, given the complete state of the world and all the laws of nature, and the choice occurs without any further causal input, i.e., without anything else being significantly causally relevant to which option is chosen.

Given this, we can say that *TDW-indeterminism* is the view that some of our torn decisions are TDW-undetermined. And now, given all of these definitions, I can reformulate thesis (L) as follows:

> *Central-Libertarian-Thesis*: If our torn decisions are undetermined in the right way – i.e., if they're wholly undetermined, or TDW-undetermined – then we author and control them, and they're appropriately nonrandom and L-free. Or more succinctly: *If TDW-indeterminism is true, then libertarianism is true.*

I argued for this thesis at length in a recent book (2010). I can't rehearse the whole argument here, but I'd like to provide brief formulations of two (related) arguments for Central-Libertarian-Thesis.

The first argument is easier to articulate if we assume a weak, token-token mind-brain identity theory – or more precisely, if we assume that ordinary human decisions are neural events. I don't actually need this assumption, but it makes the argument run more smoothly. In any event, given this background assumption, let's look at an example of a torn decision. Suppose that Ralph has to choose between two options, O and P, and suppose that he makes a torn decision to go with O rather than P. The details don't matter; option O could be something important like a new job, or it could be something trivial like a chocolate ice cream cone. All that matters is that Ralph makes a conscious torn decision to go with option O. Given this, if we assume that Ralph's decision was TDW-undetermined, then we get the following results:

A. Ralph's choice was conscious, intentional, and purposeful, with an actish phenomenology – in short, it *was* a Ralph-consciously-choosing event, or a Ralph-consciously-doing event (we actually know all of this independently of whether the choice was TDW-undetermined).
B. The choice flowed out of Ralph's conscious reasons and thought in a nondeterministically event-causal way.
C. Nothing external to Ralph's conscious reasons and thought had any significant causal influence (at the moment of choice – i.e., after he moved into a torn state and was about to make his decision) over how he chose, so that the conscious choice itself *was* the event that settled which option was chosen. (If you like, we can put it this way: The conscious choice itself *was* the undetermined physical event that settled which option was chosen.)

My first argument for Central-Libertarian-Thesis is based on the observation that, given (A)–(C), it seems to make sense to say that Ralph authored and controlled his decision. For (A)–(C) seem to give us the twofold result that (i) *Ralph did it and* (ii) *nothing made him do it*; and, intuitively, it seems that (i) and (ii) are sufficient for authorship and control.

Now, to get the result that Ralph's decision is appropriately nonrandom and L-free, we also need to argue that (a) his decision satisfies the other conditions for appropriate nonrandomness, aside from authorship and control (i.e., rationality, the plurality conditions, and so on), and (b) the fact that Ralph's decision is TDW-undetermined *procures* the result that it's appropriately nonrandom and L-free. Point (a) is actually very easy to argue for; I don't have the space to get into this here, but see Balaguer (2010). Point (b), on the other hand, should already be clear from the above argument; for the fact that Ralph's decision was TDW-undetermined played a crucial role in the argument for the claim that he authored and controlled the decision. It's *because* the decision was TDW-undetermined that we get the result that nothing made Ralph choose O over P. Now, it's important to note that the idea here isn't that TDW-indeterminacy actively *generates* authorship and control; the idea is rather that it *blocks a destroyer* of authorship and control. The destroyer of authorship and control would be a moment-of-choice causal influence from something external to the

agent's conscious reasons and thought. But TDW-indeterminacy rules out the possibility of such a destroyer – if a torn decision is TDW-undetermined, then at the moment of choice, nothing external to the agent's conscious reasons and thought comes in and causally influences which option is chosen – and this is why TDW-indeterminacy can be seen as *procuring* authorship and control.

My second argument for Central-Libertarian-Thesis is based on the fact that when we make torn decisions, it *feels* as if we author and control them. The argument can be put like this:

1. The only initially plausible reason to doubt the phenomenology of our torn decisions – i.e., the only reason to doubt our feeling that we author and control these decisions – is that it might be that, unbeknownst to us, our torn decisions are causally influenced (at the moment of choice) by events that are external to our conscious reasons and thought in a way that's inconsistent with the idea that we author and control these decisions. (For example, it could be that our torn decisions are deterministically caused by wholly non-mental brain events that precede our torn decisions in our heads.) But
2. If our torn decisions are TDW-undetermined, then they're *not* causally influenced (at the moment of choice) by anything external to our conscious reasons and thought. Thus,
3. The assumption that our torn decisions are TDW-undetermined seems to eliminate the only initially plausible worry we might have about the accuracy of the phenomenology of our torn decisions. Therefore, it seems plausible to conclude that
4. *If* our torn decisions are TDW-undetermined, then the phenomenology of our torn decisions is accurate and, hence, we author and control these decisions; moreover, it should be clear that the TDW-indeterminacy is *procuring* the authorship and control here, and so we get the result that if our torn decisions are TDW-undetermined, then they're also appropriately nonrandom and L-free.[3] In other words, we get the result that
5. Central-Libertarian-Thesis is true.

The two arguments for Central-Libertarian-Thesis that I just articulated are obviously very quick, and there are a number of different worries that one might have about them. I won't be able to respond to all of these worries here, but I'd like to say a few words about two of them. I'll start with this one:

> *The Rollback Objection*: Suppose that Ralph is torn between two options, O and P, and eventually chooses O in a torn decision sort of way. And now suppose that God "rolls back" the universe and "replays" the decision. If the decision is undetermined at the moment of choice, then it seems that the decision might very well go differently the second time around, even if everything about the past – in particular, everything about Ralph and his reasons – remained the same. Indeed, if the decision is TDW-undetermined, then it seems that if God "played" the decision 100 times, we should expect that Ralph would choose

[3]Actually, to fully motivate (4), we would also need to argue that if our torn decisions are TDW-undetermined, then they satisfy the other requirements for appropriate nonrandomness, i.e., rationality and the plurality conditions. But, again, this point is easy to argue; see Balaguer (2010), Sects. 3.3.4–3.3.5.

O and P about 50 times each. But given this – given that Ralph would choose differently in different "plays" of the decision, without *anything* about his psychology changing – it's hard to see how we can maintain that Ralph authored and controlled the decision. It seems to be a matter of *chance* or *luck* what he chose, and to the extent that this is right, it seems that Ralph didn't author or control the choice.

The first point I want to make in response to this objection is that it simply doesn't follow from the fact that Ralph would choose differently in different "plays" of the decision that he didn't author or control the decision. There is no inconsistency in claiming that (a) Ralph chooses differently in different plays of the decision and (b) in each of the different plays of the decision, it is *Ralph* who does the choosing and who authors and controls the choice. Indeed, given that Ralph is making a *torn* decision, the hypothesis that it's *him* who's making the decision (or who's authoring and controlling the decision) seems to *predict* that he would choose differently in different plays of the decision. It would seem very suspicious if he always chose the same option in the various plays of the decision; in that scenario, it would be plausible to think: "That can't be a coincidence; something must be *causing* him to choose that way; and since (by assumption) his conscious reasons and thought aren't causing this, it must be something else, e.g., a random, non-mental event in his nervous system, or a subconscious mental state." But if Ralph chose *differently* in different plays of the decision, that would fit perfectly with the hypothesis that the choice is flowing from *him*, or from his conscious reasons and thought; for since Ralph is making a torn decision, we know by assumption that he is neutral between his two live options, at least in his conscious thought. Thus, it seems to me that since Ralph is torn, if he chose differently in different plays of the universe, that wouldn't undermine the hypothesis that he authors and controls the decision; on the contrary, it would *confirm* that hypothesis.

(You might think that if there was a fixed probability that Ralph was going to choose option O – or, more specifically, if there was a 0.5 probability that he would choose O and a 0.5 probability that he would choose P – then it was just a matter of luck that he in fact *did* choose O, and so it couldn't be that he authored and controlled the decision. My response to this is that if Ralph's decision was TDW-undetermined, then (i) it was *his reasons* that caused it to be the case that the probabilities in question were 0.5, and (ii) despite the fact that there were fixed probabilities here, it is still true that the choosing of O over P was done *by Ralph*, because the event in question *was* a Ralph-consciously-choosing event, and this event wasn't causally influenced by anything external to Ralph's conscious reasons and thought.)

The second objection I want to consider here is the following:

The Agent-Causal Objection: The notion of control that you're working with (and the notion of authorship too, but let's just focus on the case of control) is too weak. Something more substantive is needed for control. In particular, it seems that something like agent causation is needed. In other words, when someone makes a torn decision, in order for it to be the case that the agent in question controls which option is chosen, it needs to be the case that he or she *causes* the given option to be chosen.[4]

[4]Pereboom raises a worry like this about my view in his (forthcoming).

I think it can be argued that agent causation just *isn't* needed for authorship and control, but I won't try to argue this point here. Rather, I want to argue that in the present context, the question of whether agent causation is required for authorship and control doesn't really matter. To bring this out, let me start by distinguishing two different kinds of control – *causal-control* and *noncausal-control* – where the former requires agent causation (or something like it) and the latter doesn't. I won't try to give precise definitions of these two notions; all I'll say (and all that will matter here) is that when I use the term "noncausal-control," I'm talking about a kind of control that applies to ordinary torn decisions if they're TDW-undetermined; i.e., it applies to torn decisions like Ralph's, where the agent makes a conscious decision with an actish phenomenology and which option is chosen isn't significantly causally influenced (at the moment of choice) by anything external to the agent's conscious reasons and thought, so that the conscious choice itself *is* the event that settles which option is chosen. Beyond this (and beyond the fact that causal-control requires agent causation and noncausal-control doesn't), it won't matter how exactly these two kinds of control are defined. But for the sake of argument, let's pretend that we've got two precisely defined kinds of control here. Given this, one question we might ask is the following:

> *The what-is-control question*: What is control? That is, which of the various kinds of control that we find in the literature is *real* control? Is causal-control real control? Is noncausal-control? Are both? Is neither?

But why should libertarians care about this question? They don't need to claim that if our torn decisions are TDW-undetermined, then they're authored and controlled by us and L-free in the only senses of these terms that anyone might care about, or in the senses of these terms that philosophers have traditionally cared about. All they need is this:

> (*) If our torn decisions are TDW-undetermined, then they're authored and controlled by us and appropriately nonrandom and L-free in interesting and important ways that are worth wanting and worth arguing for and that libertarians can hold up and say, "This gives us a noteworthy kind of libertarian free will."

Now, don't take me to be saying more than I am here. I'm not saying that libertarians can define authorship and control and L-freedom *however they want to*; they can't just define these terms in ridiculously weak ways and then claim victory. I don't need to argue that the kind of L-freedom I've articulated – the kind that we get if our torn decisions are TDW-undetermined (i.e., the kind that involves noncausal-control) – is the one and only kind of L-freedom that anyone might care about. But I do need it to be the case that this kind of L-freedom is interesting, worth wanting, worth arguing for, and so on. In other words, I need (*).

But I think the above arguments for Central-Libertarian-Thesis do motivate (*). Let's return to Ralph's decision. If it's TDW-undetermined, then (a) the choice was conscious, intentional, and purposeful, with an actish phenomenology – in short,

it *was* a Ralph-consciously-choosing event, or a Ralph-consciously-doing event; and (b) the choice flowed out of Ralph's conscious reasons and thought in a nondeterministically event-causal way; and (c) nothing external to Ralph's conscious reasons and thought had any significant causal influence (after he moved into a torn state and was about to make his decision) over how he chose, so that the conscious choice itself *was* the event that settled which option was chosen. This might not give us every kind of L-freedom you might have wanted, but it clearly gives us *one important kind* of L-freedom – a kind that libertarians can hang their hats on and that's worth wanting and arguing for and so on. After all, in this scenario, the event that settles which option is chosen *is* the conscious decision – i.e., it's the event with a me-consciously-choosing-now phenomenology.

There is obviously a lot more to say about all of this. In Balaguer (2010), I develop the arguments for Central-Libertarian-Thesis a lot more thoroughly, and I respond to a number of different objections to these arguments. For instance, I say more by way of response to the luck objection; and I respond to the worry that the kind of L-freedom I've been describing here isn't robust enough to give us moral responsibility; and I also respond to the worry that this kind of L-freedom isn't worth wanting because torn decisions are trivial. Unfortunately, though, I don't have the space to discuss these issues here.

In any event, if what I've argued in this section is correct, then we have the result that if TDW-indeterminism is true (i.e., if some of our torn decisions are TDW-undetermined), then libertarianism is also true (i.e., humans are L-free). But given this, it follows pretty quickly that the question of whether libertarianism is true just reduces to the question of whether TDW-indeterminism is true.[5] And if this is right, then we have an answer to the main question of this section: The determinism question is definitely relevant to the libertarian question.

[5]To argue for this, libertarians need to argue that if TDW-indeterminism *isn't* true, then libertarianism isn't true either – i.e., that if our torn decisions aren't TDW-undetermined, then we aren't L-free. Now, you might doubt this, because you might think that even if our torn decisions aren't L-free, some of our non-torn decisions could be L-free. But it's pretty easy to argue – and I do argue for this point in Balaguer (2010) – that if none of our torn decisions is L-free, then it's very likely that we don't make any L-free choices at all. The more important worry about the above thesis (i.e., the thesis that if TDW-indeterminism isn't true, then libertarianism isn't true either) is that even if our torn decisions aren't TDW-undetermined (i.e., even if they aren't *wholly* undetermined), they could still be *partially* undetermined in a certain way. To say that a torn decision is partially undetermined in the sense I have in mind here – or what comes to the same thing, partially determined – is to say that, at the moment of choice, factors external to the agent's conscious reasons and thought causally influence (but don't causally determine) which tied-for-best option is chosen. I think it can be argued that if our torn decisions are partially undetermined in this way, then they're also *partially L-free*. Thus, to be precise, what we need to say here is not that if TDW-indeterminism isn't true, then we aren't L-free, but that if TDW-indeterminism isn't true, then we aren't *fully* L-free. And so to get the result that if TDW-indeterminism isn't true, then libertarianism isn't true, we need to be clear that we're defining libertarianism as the view that humans are *fully* L-free.

Is There Any Good Reason to Doubt that Our Torn Decisions Are TDW-Undetermined?

We found in the last section that the question of whether libertarianism is true boils down to the question of whether TDW-indeterminism is true (i.e., the question of whether some of our torn decisions are TDW-undetermined). In this section, I want to discuss the question of whether we have any good reason to reject TDW-indeterminism. I think it's pretty obvious that, at present, we don't have any good reason to *endorse* TDW-indeterminism, but you might think we have good reason to *reject* it, because you might think we have good reason to endorse some deterministic thesis that's incompatible with TDW-indeterminism. I will argue in this section, however, that as of right now, we don't have any good reason to believe any such deterministic thesis.

Is There Any Good Reason to Believe Universal Determinism?

Let *universal determinism* (or UD) be the thesis that I've been calling "determinism" – i.e., the thesis that every event is causally necessitated by prior events together with causal laws. It's pretty easy to see that as of right now, we don't have any good reason to believe UD. For UD is true only if all quantum events are determined, and as of right now, we don't have any good reason to believe that all quantum events are determined. The first point to be made here is that quantum mechanics (or QM) contains probabilistic laws; it tells us, for instance, that if an electron is spin-up in a particular direction x, then it's in a superposition state with respect to its spin in the orthogonal direction y, and if we measure it for spin in the y-direction, then it will collapse into either a spin-up state or a spin-down state, and there's a 0.5 probability that it will collapse into a spin-up state and a 0.5 probability that it will collapse into a spin-down state.

Now, of course, the fact that QM contains probabilistic laws of this kind does not by itself give us reason to doubt UD; for it could be that there are hidden facts (or as physicists say, *hidden variables*) about electrons that are spin-up in the x-direction that determine whether they will collapse into a spin-up state or a spin-down state when measured for spin in the y-direction. But the problem is that there is no good evidence for the existence of hidden variables of this kind, and so, for all we know, it could just as easily be that when electrons that are spin-up in the x-direction are measured for spin in the y-direction, *nothing* determines whether they collapse into a spin-up state or a spin-down state; in other words, for all we know, it could be that events of this kind – i.e., events involving quantum wave-function collapses – are genuinely undetermined.

This is not to say that we have good reason to endorse an indeterministic view of these events. Rather, it's to say that as of right now, we have no good reason to reject an indeterministic view. In other words, the question of whether these quantum collapse events are genuinely undetermined or just apparently undetermined (i.e., really determined) is an open question. There is simply no good evidence on either side of the debate. Or to put the point differently, there's

no good evidence for any (deterministic or indeterministic) interpretation of QM. An interpretation of QM is essentially a theory of what's going on in quantum collapse events of the above kind; there are numerous interpretations in the literature, some deterministic and some indeterministic, but at present, there isn't any evidence for any of them, and more generally, there isn't any compelling reason to endorse a deterministic or an indeterministic view of quantum collapse events.[6]

Is There Any Good Reason to Believe Macro-Level Determinism?

If the arguments of the previous section are cogent, then there's no good reason to believe universal determinism. But in order to undermine TDW-indeterminism and libertarianism, you don't need to motivate universal determinism. Since TDW-indeterminism is about torn decisions only, you could undermine this thesis by arguing for the much weaker claim that all torn decisions are determined. One way to do this would be to point out that torn decisions are macro-level events and then argue for *macro-level determinism*, i.e., the view that all macro-level events are determined. Or, alternatively, you could undermine TDW-indeterminism by arguing for what might be called *virtual macro-level determinism*, i.e., the view that while it may be that some macro-level events are strictly undetermined (because they're composed of micro-level events, some of which are undetermined), it's also true that all macro-level events are, if not determined, at least virtually determined (where an event is *virtually determined* iff prior circumstances together with causal laws made it overwhelmingly likely that the given event would occur). In other words, the idea here is that while there may be some micro-level indeterminacies, these all "cancel out" before we get to the macro level, presumably because macro-level phenomena are composed of such large numbers of micro-level phenomena. (It should be clear that virtual macro-level determinism would undermine TDW-indeterminism; after all, it entails that all torn decisions are virtually determined, i.e., that for any torn decision, there's a unique option X such that prior events made it overwhelmingly likely that X would be chosen.)

The question I want to ask now is whether we have any good reason to believe macro-level determinism or virtual macro-level determinism. People sometimes claim that there's a good inductive argument for macro-level determinism (see, e.g., Honderich (2002)[7]). We might put the argument here as follows:

1. All the macro-level events that we have encountered have been causally determined by prior events together with causal laws. Therefore,
2. Macro-level determinism is true – i.e., all macro-level events are determined.

[6]Of course, there are people who favor certain interpretations over others, but there is pretty widespread agreement among those who work on the foundations of quantum mechanics that we do not have any solid evidence for any of the various interpretations and that when people embrace these interpretations, they are engaged in speculation.

[7]Actually, Honderich thinks we can use arguments like the one in the text to motivate not just macro-level determinism but universal determinism as well.

But this argument is misguided. In particular, premise (1) is unmotivated, controversial, and question begging. We encounter all sorts of macro-level events that, for all we know, could be undetermined – coin tosses, events in which a person contracts chicken pox from someone else, events in which macro-level measuring devices reveal quantum wave-function collapses, human decisions, chimp decisions, parakeet decisions, temper tantrums, etc. Now, of course, determinists have a story to tell about how it *could be* that events like these are deterministic; e.g., they can claim that if, say, Jack and Jill were both exposed to chicken pox and only Jack fell ill, this would not undermine determinism because it could be that there were hidden physical variables at work in the situation (e.g., factors having to do with the physical well-being of Jack and Jill, or the duration of their exposures, or whatever) that determined that Jack would contract the disease and Jill would not. And likewise for events of the other kinds listed above; determinists can say that events like coin tosses and decisions could be determined even if they don't seem determined to us, because it could be that there are hidden determining factors at work in such cases. I agree; for all we know, it *could be* that events of the above kinds are determined. But in the present context, this is entirely irrelevant. What advocates of the argument in (1)–(2) need isn't a story about how it *could be* that events of the above kinds are determined; what they need is a positive argument for the claim that, in fact, such events *are* determined.

But I take it that determinists don't have an argument of this kind. The argument they used to give here is that any apparently indeterministic behavior in macro-level systems must really be deterministic, because such systems are made up of micro-level systems whose behavior is deterministic. But this argument is no good, because (as we've seen) we currently have no more reason to believe micro-level determinism than macro-level determinism.

Now, I suppose one might respond here by claiming that every time we go looking for deterministic explanations, we find them. But this is just false. It's not just that we don't currently have deterministic explanations of events of the above kinds; it's that we haven't the foggiest idea how to proceed in trying to construct and justify such explanations.

The situation with virtual macro-level determinism is similar. One might try to argue for this view by saying something like the following:

1′. All the macro-level events that we've encountered have been either determined or virtually determined. Therefore,

2′. Virtual macro-level determinism is true – i.e., all macro-level events are either determined or virtually determined.

But this argument is flawed in the same way the (1)–(2) argument is flawed. In short, the problem is that (1′) is unmotivated, controversial, and question begging. There are lots of macro-level events – coin tosses, quantum-measurement events, decisions, and so on – that, for all we know, are neither determined nor virtually determined. In order for virtual macro-level determinists to motivate an inductive argument of the above kind, they would need to provide positive reasons for thinking that events like coin tosses and decisions and quantum measurements

are, in fact, either determined or virtually determined. But at present, there is simply no good reason to believe this.

Finally, it's worth noting here that if the remarks in this section are correct, they suggest not just that the above inductive arguments are noncogent, but that, right now, we don't have any good reason to believe macro-level determinism or virtual macro-level determinism.

Is There Any Good Reason to Believe Neural Determinism?

Since torn decisions are presumably neural events, you might think that we could undermine TDW-indeterminism (and hence libertarianism) by uncovering reasons to believe *neural determinism* (i.e., the view that all neural events are determined) or *virtual neural determinism* (i.e., the view that all neural events are either determined or virtually determined in the sense defined above). But, in fact, we don't have any good reason to believe either of these theses. If current neuroscientific theory were deterministic (or virtually deterministic), then we might be able to motivate neural determinism (or virtual neural determinism). But current neuroscientific theory is *not* deterministic (or virtually deterministic). Indeed, it treats a number of different neural processes probabilistically – e.g., synaptic transmission and spike firing. Consider, e.g., the following passages from a recent textbook on neuroscience (Dayan and Abbott 2001):

> I. . . . [synaptic] transmitter release is a stochastic process. Release of transmitter at a presynaptic terminal does not necessarily occur every time an action potential arrives and, conversely, spontaneous release can occur even in the absence of the depolarization due to an action potential. (p. 179)
>
> II. Because the sequence of action potentials generated by a given stimulus varies from trial to trial, neuronal responses are typically treated statistically or probabilistically. For example, they may be characterized by firing rates, rather than as specific spike sequences. (p. 9)

It is worth noting that some aspects of the indeterminacies in these processes (or the apparent indeterminacies, as the case may be) are caused by the indeterminacy (or apparent indeterminacy) in another process, namely, the opening and closing of ion channels. Now, to be sure, by treating these processes probabilistically, neuroscientists don't commit themselves to the thesis that, in the end, they are genuinely indeterministic. But the important point here is that they aren't committed to determinism either. The question of whether these processes are genuinely indeterministic simply isn't answered by neuroscientific theory. Indeed, it is a standard view among those who work in this area that for at least some of these processes (e.g., the opening and closing of ion channels), this isn't even a neuroscientific question, because it is already clear right now that there could not be deterministic neuroscientific explanations of the phenomena. In other words, the idea is that (a) from the point of view of neuroscience, these processes might as well be undetermined but (b) it *could* be that there are underlying

deterministic *physical* explanations of the phenomena. Thus, the question of whether there actually are such explanations is not a neuroscientific question at all; it is rather a question of physics, because the issue comes down to questions about the behavior of the elementary physical particles involved in the neural processes.

It sum, then, it seems to me that neuroscientific theory is neither deterministic nor virtually deterministic, and so it doesn't give us any reason to believe neural determinism or virtual neural determinism. And given this, it seems safe to conclude that as of right now, we don't have any good reason to believe neural determinism or virtual neural determinism.

Is There Any Good Reason to Believe Torn-Decision Determinism?

Finally, you might try to undermine TDW-indeterminism by arguing for *torn-decision determinism* (i.e., the view that all torn decisions are determined) or *virtual torn-decision determinism* (i.e., the view that all torn decisions are either determined or virtually determined). Or, of course, you could try to argue directly against TDW-indeterminism; i.e., you could try to give a direct argument for the claim that none of our torn decisions is TDW-undetermined. In this section, I will respond to one such argument, an argument based on the work of Benjamin Libet.

(It's worth noting that the argument based on Libet's work isn't the only argument against TDW-indeterminism that one might consider here. Another important argument – we might take it to be an argument for something like virtual torn-decision determinism – is based on Max Tegmark's (2000) argument for the claim that if there are any neural superposition states, they couldn't survive long enough to be affected by neural processes. One might also construct arguments against TDW-indeterminism by using considerations having to do with situationism (see, e.g., Isen and Levin 1972, Milgram 1969, and Nelkin 2005), the sluggishness of consciousness (see, e.g., Velmans 1991 and Wegner 2002), or the way in which humans are often out of touch with the real underlying reasons for their actions (see, e.g., Festinger 1957). In Balaguer (2010), I argue that none of these considerations provides us with any good reason to reject TDW-indeterminism; but unfortunately, I don't have the space to pursue any of this here.)

In any event, let's consider the argument against TDW-indeterminism that's based on Libet's work. Libet's studies were a follow-up to a neuroscientific discovery from the 1960s, in particular, the discovery that voluntary decisions are preceded in the brain by a slow change in electrical potential known as the *readiness potential* (see, e.g., Kornhuber and Deecke 1965). Libet's studies were an attempt to establish a timeline for the readiness potential, the conscious intention to act, and the act itself (see, e.g., Libet et al. 1983, and Libet 2002). His results suggest that the readiness potential appears about 350–400 milliseconds before the conscious intention to act and about 550 milliseconds before the act itself.

And given this, one might argue against TDW-indeterminism in something like the following way:

1. Conscious decisions are preceded by nonconscious brain processes (namely, the readiness potential) and are, in fact, nonconsciously initiated. Therefore, it seems likely that
2. Torn decisions are at least causally influenced by prior-to-choice nonconscious brain processes, and so they are not TDW-undetermined; indeed, they might be determined, or virtually determined, by prior-to-conscious-choice brain processes.

In other words, the idea here is that our torn decisions couldn't be TDW-undetermined because (to borrow Henrik Walter's (2001) phrasing) the "neural machinery" for starting our decisions is already up and running before our conscious thinking enters the picture.

One might try to attack the argument in (1)–(2) by questioning (1), but I won't pursue this strategy here. What I want to argue instead is that even if (1) is true, it does not give us any good reason to accept (2). The first point to note here is that we don't know what the *function* of the readiness potential is. In particular, it would be an unmotivated assumption to suppose that, in torn decisions, the readiness potential is part of a causal process that's relevant to which option is chosen. There are plenty of other things the readiness potential could be doing, aside from this. One way to appreciate this is to notice that libertarianism is perfectly consistent with the idea that various things involved with our torn decisions might be causally determined. In particular, a torn decision could be L-free even if it was determined in advance that (i) a torn decision would occur, and (ii) the choice would come from among the agent's reasons-based tied-for-best options, and (iii) the moment-of-choice probabilities of these options being chosen were all roughly even. The only thing that needs to be undetermined, in order for a torn decision to be L-free, is *which tied-for-best option is chosen*. Given this, here are two stories libertarians could tell about what the readiness potential could be doing (there are other stories as well – see, e.g., Mele (2009) – but these two will do):

Model A: (a) The readiness potential is part of the causal process leading to the *occurrences* of torn decisions, and this has nothing whatsoever to do with which option is chosen; and (b) which option is chosen is in fact TDW-undetermined. (A similar point, though a bit different, has been made by Haggard and Eimer – see, e.g., their (1999) as well as Haggard's contribution to Haggard and Libet (2001).)

Model B: (a) The readiness potential is part of the process whereby our reasons cause our decisions, and (b) in connection with torn decisions, this process doesn't determine which option is chosen; rather, it deterministically causes it to be the case that the choice will come from among the reasons-based tied-for-best options (and perhaps also that the moment-of-choice probabilities of these options being chosen are all roughly even).

Now, models A and B are both highly controversial, and as of right now, I don't think we have any good reason to endorse either of them. But the important

point here is that as of right now, we don't have any good reason to reject them either; in particular, the available evidence concerning the readiness potential doesn't give us any good reason to reject them. More generally – and in the present context, this is the really important point – as of right now, there is no reason to think that, in torn decisions, the readiness potential is part of a causal process that's relevant to the issue of which tied-for-best option is chosen. There is simply no evidence for this, and so the existence of the readiness potential doesn't give us any good reason to suppose that, in torn decisions, which tied-for-best option is chosen is causally influenced by prior-to-choice nonconscious brain processes.

Conclusion

In the last section, I responded to a variety of arguments against TDW-indeterminism. There are, of course, other arguments that one might attempt here, but I don't think any of them are cogent. In other words, at the present time, I don't think we have any good reason to reject TDW-indeterminism. And as I pointed out above, I don't think we have any good reason to *endorse* TDW-indeterminism either. Thus, if this is right, then the question of whether TDW-indeterminism is true is a wide open question. But earlier I argued that the question of whether libertarianism is true (i.e., the question of whether humans are L-free) reduces to the question of whether TDW-indeterminism is true. Thus, it seems that as of right now, the libertarian question is an open question. And in particular, it's an open *empirical* question. For (a) the question of whether we're L-free turns on the question of whether TDW-indeterminism is true, and (b) TDW-indeterminism is a straightforward empirical hypothesis about the causal histories of our torn decisions.

No Excuses: Performance Mistakes in Morality

Abstract

Philosophical accounts of moral responsibility are standardly framed by two platitudes. According to them, blame requires the presence of a moral defect in the agent and the absence of excuses. In this chapter, this kind of approach is challenged. It is argued that (a) people sometimes violate moral norms due to performance mistakes, (b) it often appears reasonable to hold them responsible for it, and (c) their mistakes cannot be traced to their moral qualities or to the presence of excuses. In the end, the implications for discussions of moral responsibility are discussed.

Associated Press report Posted: 01/25/2013 08:18:46 AM MSTCOLONIE, N.Y. (AP) – Authorities say a New York man who left his 1-year-old son in his car for eight hours in frigid weather only realized his mistake after a call from his wife. Police in the Albany suburb of Colonie say the man forgot to drop off his son at day care and left the child strapped in the backseat of the car when he parked outside his office Thursday morning.

Introduction

Philosophical accounts of moral responsibility for wrongdoing are standardly framed by two platitudes. The first, the *positive condition*, holds that attribution of responsibility, and the associated assignment of blame, requires the *presence* in the agent of a moral defect implicated in the wrongdoing.[1] The second, the *negative condition*, requires the *absence* of excuses, such as ignorance or coercion.[2] If either condition fails to apply, the attribution of responsibility is blocked.

It is easy to see why the platitudes are platitudes. If a person's violation of a moral norm is sourced in some feature of their being that is not a moral defect – say, a mental disorder – or if a violation is committed in excusing conditions – say, under extreme duress – it is difficult to see why they should be blamed for it. Like many others, we are strongly inclined to endorse this picture. At the same time, we acknowledge the existence of a variety of *performance mistakes* in the realm of morality, where (1) people violate moral norms, (2) it appears reasonable to hold them responsible for these violations, and (3) neither of the two platitudes apply.

Something has to go. While what goes, as in other trilemmas of this kind, is a matter of contestable philosophical discretion, we will argue that neither the fact of the moral violation nor the appropriateness of responsibility attribution is readily contested. If so, it would seem that the platitudes must be discarded or revised. Given their status as platitudes, this result is of no small importance.

Our argument goes as follows. First, we introduce the notion of performance mistakes and show why they are sometimes violations of moral norms for which the actor is morally responsible. Second, we claim that these mistakes can be understood in terms of failures to exercise normative competence. With this understanding in hand, we next discuss two varieties of performance mistakes and explain why the positive and negative conditions are not there met. Finally, after having articulated the trilemma, we hint at our preferred way of addressing it.

Performance Mistakes

Performance mistakes have figured in theorizing about the human mind since the "cognitive revolution" that marked the demise of behaviorism. In his paper, "The Problem of Serial Order in Behavior," Lashley (1951) offered a disarmingly simple,

---

[1]The positive condition takes a variety of forms: Humeans require bad character (Brandt 1958; Nozick 1981), Kantians require a deficient will, (Wolff 1990; Wallace 1994), and followers of Frankfurt require motivations with origins in the "real self" (Scanlon 1998; Smith 2005). For an account of the condition that is meant to be neutral between the moral psychological pictures underlying these views, see McKenna (2012).

[2]If anything, the second platitude is even more of a platitude than the first. For examples, refer to the references given in parenthesis (Austin 1962; Wallace 1994; Baron 2007; Franklin 2011; McKenna 2012) The standard excuses are sometimes referred to as "Aristotelian conditions," after Aristotle's discussion in *Nichomachean Ethics* III.

yet extremely effective, argument against behaviorist accounts of linguistic behavior. As he noted, stimulus–response theories were utterly unable to explain a variety of performance mistakes, in particular, simple linguistic mistakes. What, Lashley asked, would be the stimulus–response explanation of the mistake in which a competent speaker reverses the order of two utterances in a spoonerism (saying "queer old Dean" instead of "dear old Queen")?

Years later, Chomsky (1959) recognized the value of this insight in his "Review of Skinner's Verbal Behavior." Lashley, in his opinion, had identified behaviorism's major blind spot: The production of grammatical utterances is not simply a matter of chained responses to stimuli, but requires implementing an abstract linguistic structure not easily read off speakers' performance. Verbal performance requires, in other words, linguistic *competence*, which Chomsky identified with tacit knowledge of a grammar, together with whatever cognitive and executive mechanisms are required for translating that general knowledge into linguistic behavior.[3]

Obviously, there are important differences between verbal and moral performances. But there are also significant parallels, as has been noted by numerous philosophers advocating "The Linguistic Analogy," the thesis that moral cognition and behavior are structurally similar to the knowledge and the deployment of a grammar in everyday speech (Harman 1999; Mallon 2008; Mikhail 2010; Roedder and Harman 2010). In the present context, the Linguistic Analogy provides a model for thinking about how moral agents can fail to behave in appropriate ways, despite having the required moral competences. Morally responsible behavior is made possible by the fact that people have a grasp of what is morally required from them and the further ability to implement that understanding in what they do. Thus, when an informed and able person makes a moral mistake, there are (at least) two possibilities. The mistake can morally impugn her motivations and sensibilities, or it can simply be a mistake in translating her moral understanding into behavior. If the later is the case, the mistake will be, like the common verbal lapses Lashley remarked upon, a performance mistake.

Moral performance mistakes should be clearly distinguished from other kinds of moral failure. For instance, to the extent that these are mistakes and not simple failures, only agents with basic moral competences can make them. So, they are unlike the failures of very young children or impaired adults, who cannot understand moral requirements or shape their behavior accordingly. Also, the moral transgressions in them are not intentional. Thus, they differ from instances of willfully malicious behavior (even from cases in which the person behaves wrongly without intent but knowingly). Lastly, to the extent that the mistakes are genuine performance mistakes, their occurrence cannot be traced to a lack of moral concern on the part of their agents; they are not instances of indifference, callousness, or the like.

Let us make this more concrete by outlining various ways in which moral performance mistakes can occur. Sometimes a thought that would normally occur

[3]Hence, Chomsky proposed a division of labor between theories of competence in linguistics and theories of performance (1965, pp. 3–4; 1964, pp. 9–10).

to you does not cross your mind; say, it simply does not occur to you to help a distressed pedestrian you see on the street (Matthews and Cannon 1975; Cohen and Spacapan 1984). Other times, the agent loses track of what she is doing; planning on dropping his child at day care on the way to work, a father winds up driving straight to the office, leaving his child in the backseat of the car all day (McLaren et al. 2005; Weingarten 2009). These and similar mistakes, it turns out, are commonplace, and sometimes have catastrophic consequences.

A central goal for theories of moral responsibility is to set criteria for responding to the behaviors of morally competent agents. At least, this is what many philosophers inspired by Peter Strawson (1962/1982) have sought to provide.[4] According to this line, when someone is appropriately attributed responsibility, the person is appropriately held to be a target of what Strawson called the *reactive attitudes*. These are a class of evaluative responses bound up with expectations about how people ought to behave toward each other, a class that includes blame-related attitudes such as indignation and forgiveness, as well as praise-related ones such as admiration and gratitude.

For the most part, responsibility theorists have focused on voluntary mistakes. If involuntary but responsible wrongdoing is discussed, the mistake is usually traced to the person's having certain disavowed biases or attitudes for which there is no good excuse. This is just an application of the *positive* and *negative* conditions for responsibility mentioned earlier.[5] Unfortunately, this schema is not easily applied to performance mistakes, despite that those who make them seem to be morally responsible for doing so and that their occurrence is normally embedded in the social practices that Strawson remarked upon.

To begin, some performance mistakes are clear cases of *wrongdoing*. The mistakes involve violations of appropriate moral norms. People are expected to help if there is a small cost in doing it, and parents are expected to not abandon their children in the car all day. At the same time, the violations are not intentional. You did not *mean* to leave your child in the car while you were at work, and the thought of *avoiding* helping did not even cross your mind. Nevertheless, you failed to display the amount of consideration or care toward someone else that was expected from someone in your position, and because of that, some of the Strawsonian *reactive attitudes* seem fitting. Resentment and indignation might seem too much. Yet, someone might reasonably be disappointed with you for not helping the pedestrian, and you would almost certainly feel guilty about having abandoned your child in the car. There may be cases where guilt is irrational, to be sure, but this certainly does not seem to be one of them: more likely there would seem to be

[4]See Vargas (2013a) for an in-depth treatment of moral responsibility from this Strawsonian perspective. Not everyone agrees with this general approach. There are, for instance, retributivist accounts that define responsibility for wrongdoing in terms of deserved suffering (Strawson 2000; Levy 2011). As it will become clear below, we contend that there are several notions in the "responsibility neighborhood," not all of which are essentially linked to punishment or reward.

[5]Examples of this trend can be found in the references given in parenthesis (Adams 1985; Scanlon 1998; Smith 2005). An exception is Sher (2006).

something amiss if, as a parent, you *failed* to feel guilt upon discovering that you left your child behind.[6]

Whether tacitly or explicitly, these attitudes seem to involve *psychological assessment*. Among the assessments that would sustain disappointment and guilt in the examples would be these: It did not occur to you to help, that you were not attending to your child, and so on. Thus, to the extent that the responses are fitting, they seem to track the fact that the actor was not in the expected state of mind. They instantiate a kind of assessment which, without being quite an evaluation of the person, still goes *beyond* the mere expression that things did not go as one would have wished (Nagel 1986, pp. 120–121; Wolff 1990, p. 41; Sher 2006, pp. 105–106). In fact, sometimes it involves putting oneself in the position of the agent and asking what kinds of considerations *ought* to have shaped one's behavior in that case.

To the extent that they are fitting, the reactive attitudes in these cases reflect the fact that in the circumstances, it was reasonable to expect the agent to behave appropriately. In this respect, they seem to track considerations of *fairness*. The mistakes do not happen because the agent was entirely lacking in the requisite capacities, or because she had only partially mastered some of the required skills, or even because their exercise required considerable effort. They happen, instead, in what one might call the agent's zone of "secure competence" (Raz 2010; Amaya in preparation). In fact, given what was required and the situation of the agent, success was not only reasonable but, as we shall see below, also *within easy reach*.

Of course, not all mistakes with significant consequences are like the performance mistakes we have been describing. Some of them *cannot* be traced to the person's being in the wrong state of mind and, thus, the psychological assessment implicit in the reactive attitudes simply cannot go through. If you trip and break a vase, plausibly, what is normally signaled by calling it a "mere accident" is that the tripping was not an indication of your state of mind at the time: You were not reckless, only clumsy. Other mistakes can be readily accounted for in terms of the *positive* condition. Their agents are not blameworthy because the relevant kind of wrongdoing is defined in terms of a specific moral defect – or, at least, a state of mind that normally indicates a defect in the agent's moral qualities – that is absent

[6]It might be objected that the attitudes that are fitting in these cases are similar, but not identical, with the reactive attitudes associated with responsibility and blame. For instance, one could argue that the fitting response in the case of child neglect is not genuine guilt but, instead, what Williams (1976) has called "agent-regret." There are complicated issues concerning the individuation of these attitudes and their relation to moral blame, which are beyond the present discussion. But if, as Williams intends, agent-regret is understood as a form of evaluation that is distinctively retrospective, agent-regret is not the attitude that fits this kind of case. *At the time* the parent had enough information to see that his behavior was inappropriate; in the light of it, what he did was *obviously* wrong. The case is, thus, unlike the examples discussed by Williams (e.g. Gaugin, the lorry driver), where the agent's decisions are regrettable or not precisely in the light of information that the agent does *not* have at the time, namely, information concerning their outcome. For discussion of the retrospective nature of agent-regret, refer to the references given in parenthesis (Williams 1976: esp. 126–128; Rosebury 1995, pp. 505–506).

in the mistake. There is, for instance, no moral blame for the clerk who gives back the wrong change simply due to an adding mistake: Theft, unlike child neglect, requires intent. Lastly, other performance mistakes are entirely excusable. Thus, the *negative* condition applies in them: A person might fail to behave appropriately because the standards were too demanding for her, or simply because the circumstances made it hard for her to live up to those standards.

Normative Competences

Philosophers who endorse the platitudes tend to agree that responsibility requires the *exercise* of certain rational competences. Put in terms of the *positive* condition, the idea is that moral defects are implicated in instances of wrongdoing, not just causally, but in the way required for responsibility and blame, by virtue of influencing what the actor finds reasonable to pursue.[7] But the point is also clear if one focuses on the *negative* condition and asks why any of the standard excuses precludes blame. Presumably, ignorance excuses to the extent that, due to lack of information, an agent cannot be reasonably expected to consider relevant reasons.

Of course, the notions of reasons and rationality are the subject of contention. But this much seems uncontroversial: A responsible agent is one that has certain kinds of normative competences (Wallace 1994, p. 226; Doris 2002, pp. 133–140), which include, at a minimum, whatever cognitive capacities are required to appreciate moral considerations, together with whatever executive capacity is required to regulate behavior in accordance with these considerations. Following standard usage in the literature, we shall henceforth refer to agents who exercise these competences as *reasons-responsive*.

Any theorist who takes the notion of reason-responsiveness as central needs to make room for the fact that people sometimes deserve blame for what would otherwise seem failures to exercise these competences. Motivated by self-interest, for instance, people sometimes disregard the interests of others; or, akratically, they give into temptation and act contrary to what they know is right. In these cases, the *positive* and *negative* conditions apply: Excessive self-interest is a defect and the presence of temptation is hardly an excuse. Thus, under the condition of reasons-responsiveness, if the agents' wrongdoing is not excusable and can be traced to a moral defect, it has to be possible to see it as an expression of which reasons they

[7]There are, of course, ways in which a moral defect can be implicated but not in the way required for responsibility and blame: if one inadvertently leaves one's child in the car on the way to do some evil work at the office. The idea that responsibility requires *exercising* certain rational competences is meant to exclude, in part, this kind of cases by defining what the *right* (i.e., non-fortuitous) relation is between wrongdoing and a moral defect. It can most perspicuously be found in so-called Reason-accounts of Kantian inspiration (Wolff 1990; Nelkin 2011). But it is also present in Frankfurtians, for whom the motivations of a real self are those whose influence in behavior the agent rationally endorses, and in Humeans, for whom the character traits implicated in responsible conduct are those that provide the agent with reasons.

are sensitive to – although not necessarily which courses of action they find most reasonable to pursue. In other words, it needs to be shown that the kinds of morally insensitive behaviors to which the platitudes apply, contrary to initial appearances, meet nonetheless the requirement of reasons-responsiveness.

John Fischer and Mark Ravizza (1998) have developed a prominent account of reasons-responsiveness designed to account for these kinds of moral insensitivity, and we shall take their account as paradigmatic here. According to it, the key for responsibility is that agents act from what they call *moderately reasons-responsive mechanisms*. The notion of mechanism is intended to include things such as conscious decision and deliberation, as well as the less reflective processes by which, say, habits and emotions shape behavior, whereas the qualification "moderately" is intended to weaken the condition in a way that allows for responsibility in cases where agents are less than ideally responsive to reasons.[8]

For Fischer and Ravizza, the requirement applies in different ways to mechanisms that realize the various cognitive and executive normative competences (1998, pp. 72–74). First, it involves the agent's exercise of a cognitive competence that they call *regular reasons-receptivity*.[9] The agent need not *recognize* all the relevant moral considerations and their relative weight, which allows blame for certain instances in which reasons are disregarded, say, due to self-interest. But her recognition of reasons must still conform to a pattern that makes sense given her values and preferences, and a general understanding of what kind of considerations count as valid moral reasons. Second, moderate reason-responsiveness involves the exercise of a kind of executive competence that they call *weak reasons-reactivity*. Motivated by competing interests, the agent may not do what she recognizes as morally reasonable. But, at the very least, if her behavior is not excusable, say, because it is being forced upon her, it has to be possible for her to act differently if she were to have enough incentives to do otherwise.

With this machinery in place, we can now outline our argument for the rest of the paper. We shall avail ourselves of the idea that responsible agency requires a moderate exercise of reasons-responsiveness to indicate why for moral performance mistakes, the *positive* and *negative* conditions fail to apply. In short, these mistakes happen when agents fail to exercise normative competences they have. Their failure to exercise them cannot be traced to moral qualities of their self.

[8]For an insightful review of the account in Fischer and Ravizza, see McKenna (2001). Among others, McKenna discusses the asymmetry between receptivity and reactivity that we discuss below, concluding that Fischer and Ravizza's requirement of weak reactivity is too weak. Here, we set aside these worries, as a strengthening of the requirement will only make our argument more straightforward.

[9]More precisely, Fischer and Ravizza require that the agent *exercise* a suitable degree of reasons-recognition, which obtains, on their view, whenever the action is brought about by a certain kind of mechanism in the agent. Thus, their account not only requires that the agent has the capacity to respond to reasons but also that such capacity be displayed to a certain degree (or "be operative" as they sometimes put it) in the workings of certain mechanisms. For an explicit statement of the view, refer to the references given in parenthesis (Fischer and Ravizza 1998, p. 53; Fischer 2006, p. 242).

And, to the extent that there were no factors preventing or making onerous their exercise, the mistakes are not excusable.

In fact, as we shall see, there are two kinds of mistakes here, corresponding to the distinction between receptivity and reactivity to reasons. First, there are *cognitive* mistakes. In them, one fails *to recognize* that certain moral considerations are germane in one's situation. But the mistake is not an indication of one's lack of acceptance of moral reasons, how they fit together, or what their relative strength is. It is rather a consequence of the cognitive routines by which, in general, social situations get structured. Second, there are *executive* mistakes. Here, one *fails to react* appropriately to reasons that one actually recognizes. But the mistake is not due to the absence of proper incentives, or to a general inability to react to those reasons. It is instead a side effect of the way in which habits and well-rehearsed routines tend to shape everyday action.

Helping Behavior

Theorists who embrace the positive condition typically emphasize moral character, reflective judgments, and personal values. Yet, there is a wealth of empirical research, now well known to philosophers, showing that moral cognition and behavior are extremely sensitive to situational factors. Arguably, this *situationist* evidence troubles traditional notions of character and personhood, but we shall not make this argument.[10] Here, we want only to illustrate a particular kind of performance mistake.

It is perhaps uncontroversial that one ought to help people in distress when there is a small cost involved in doing it. And it is perhaps equally uncontroversial that, however lenient as the requirement might be, many of us fail to live up its standards. However, the evidence suggests that these failures need not be an indication of people's deep moral convictions and motivations. Instead, there are a variety of situational factors that affect helping behavior, even on the part of people who explicitly and honestly avow values, such as compassion and care, that might reasonably be expected to promote helping. One such factor is temporal: If one is slightly late for a meeting, haste might induce one not to help someone who evidently needs it (Darley and Batson 1973). Another is social: Surrounded by an unresponsive group of people, the group's attitude might easily persuade one that help is not needed (Latané and Rodin 1969; Latané and Darley 1970).

[10]For reviews and discussion of the situationist evidence, refer to the references given in parenthesis (Ross and Nisbett 1991; Doris 2002; Miller 2003; Nahmias 2007; Merrit et al. 2010; Miller 2013; Alfano and Fairweather 2013). Elsewhere, one of us has systematically explored how this evidence raises generalized skepticism in relation to traditional notions of character and agency (Doris 2002, 2009, 2014). For discussion of how situationist evidence affects traditional accounts of responsibility, refer to the references given in parenthesis (Nelkin 2005; Vargas 2013b; Brink 2013).

It is one thing to *decide* not to help because you feel pressured about time, or because nobody else is doing it. This might show something about how you respond to moral reasons; maybe, when it comes down to it, the things that motivate you to act are not quite in synchrony with the values that you explicitly and honestly avow. And, if this is true, at least in some cases, not helping might be an expression of a moral defect, such as selfishness or callousness, giving rise to an application of the *positive* condition. Even if one is not guilty of selfishness or callousness, one might akratically forgo helping someone else, which might indicate another kind of moral defect.

It is another thing when the thought of helping *does not occur* to one, even though one typically recognizes situations where help is needed (Darley and Batson 1973, p. 107; Doris 2002, p. 138). There, it becomes harder to see how the mistake could be traced to a defect in one's character, will, or one's views about helping others. Indeed, given these things alone, it is hard to rationalize the omission. You saw an injured pedestrian in distress, you value helping others, but the question whether to help did not occur to you. *Really*?

In fact, this sort of thing seems to happen in quite ordinary circumstances. Competent moral agents often fail to recognize obvious opportunities to exhibit pro-social behaviors. And what the evidence indicates is that their lack of recognition often cannot be traced to individual traits, but it is instead a function of situational factors that do not seem to have the makings of moral reasons. That is, these are *not* factors that the agents themselves, and competent moral agents in general, would be likely to invoke in justifying their behavior, to recommend it to others, to say what was good about it, etc.

Studies of the effects of noise on interpersonal relations provide a good illustration here. In a representative experiment, Mathews and Canon (1975: study 1) found that 72 % of participants were inclined to help a confederate simply at the sight of seeing him drop a set of reading materials. However, in a situation that was exactly alike, except that the level of white noise in the room increased from 48 to 85db, which is a volume slightly higher than a telephone dial tone, the helping behavior went down to 36 % of participants.

Admittedly, in this kind of cases, it is tempting to advance explanations, seeking to trace the observed behaviors to some kind of moral defect. One, for instance, might argue that the participants in the study did consider helping, but decided against it because they wanted to escape the noise. Or one might argue that helping did not occur to them, because they are in general not very attentive to the needs of others. The problem is that, even though these explanations would help rationalize the absence of helping behavior, there is generally no additional evidence supporting them. In the study referred above, for instance, not helping did not facilitate escaping the noise – in fact, if anything, helping the confederate was the most expedient way for the participants to escape.[11]

[11](Mathews and Canon 1975, pp. 575–576). Refer to the references given in parenthesis for review of other studies (Cohen and Spacapan 1984, pp. 222–226).

More important, there seems to be an alternative explanation in the vicinity for which there is actually supporting evidence. In the presence of disturbing environmental factors, people tend to focus their attention on whatever task they are already engaged, neglecting available information that is not directly relevant for it. The phenomenon has been documented in a variety of nonsocial scenarios and abstract tasks (Cherry 1953; Broadbent 1958; Moray 1959; Wood and Cowan 1995). But there is good reason to think that it is also a factor shaping social interactions. Namely, to the extent that everyday situations do not come explicitly labeled as requiring specific prosocial behaviors, people need to exercise some kind of ethical awareness to read off what is required from them. Yet, disturbing environmental factors, such as high levels of noise, lessen attention to social cues that would otherwise indicate what the moral demands of the specific situations are (Mathews and Cannon 1975; Cohen 1978).

To test this hypothesis, Matthews and Canon conducted a further field study, in which helping behavior was again measured in low-noise (ambient noise of 50db) and high-noise (a lawn mower running at 87db) conditions (1975: Study 2). This time, they manipulated the salience of social cues: In one condition, the confederate who dropped the documents wore a cast on his right arm; in the other, he did not wear it. As before, noise level made a significant difference in observed helping. The helping cue also made a difference: Only 15 % of subjects helped the confederate with no cast, whereas 47 % helped him when he was wearing the cast. However, it only made a significant difference when ambience noise was low, which suggests that the situational factor affected behavior by pre-empting the structuring effect that social cues otherwise play.

The example illustrates the first kind of mistake we want to highlight. It is a performance mistake of a *cognitive* variety. In certain situations, due to environmental factors, people might fail to exhibit a reasonable degree of awareness and, thus, fail to see the moral dimension of the situation that lies in front of them. Their failure, however, is not indicative of their values, or a consequence of their having competing interests. They simply fail to frame the situation as one in which their moral competences are relevant. Furthermore, the failure does not seem to be evidence of a *moral defect* in their characters, or a consequence of their personal attitudes toward what is morally significant. Instead, it seems to be a function of how adult human beings generally allocate attention and frame the situations they face in the presence of disturbing environmental factors.

Recall Fischer and Ravizza's notion of regular *reasons-recognition*. According to them, being adequately responsive is a matter of acting on mechanisms that exhibit an understandable pattern of recognition of reasons, at the very least, one in which the reasons actually and potentially recognized track one's values and weighted preferences. In the kind of mistakes we are now considering, however, this evidently is not the case. The reasons recognized at the time depend upon how one interprets the situation, but the mechanisms that shape the interpretation are influenced by factors, such as ambient noise, that are of little practical significance. Their influence is not a reflection of one's values and preferences; they are not even among the kind of things that have the makings of moral reasons (Doris 2005, p. 657, 2009, p. 66).

Now, in so far as these mistakes involve a failure to exercise some of the rational competences required for moral responsibility, it would seem that the *positive* condition does not obtain: The mistakes do not show much, or anything at all, about one's moral qualities as a person. On the other hand, the *negative* condition does not seem to apply either. To be sure, the presence of situational factors might excuse in the sense of being a mitigating consideration. Their presence prevents tracing the mistake to a moral defect in the agent. Yet, it does not seem that the standard excuses work here, as implied by the *negative* condition, by making it unfair to hold the person responsible.

To see this, begin with *duress*. Intuitively, the presence of ambient noise is not coercive in the way in which having a gun pointed to one's head is. Yet, in so far as noise affects helping behavior in a significant number of cases, one might be inclined to conclude that the pressure is intense enough to make the corresponding moral violations excusable. The problem is that statistical considerations like this are hardly ever, at least not by themselves, sufficient to indicate that behaving appropriately posed an onerous demand. Overstaying a parking meter, for example, is common, but the fact that it happens often gives no reason to suppose that the infractions occur under duress.

There are undoubtedly situational pressures that are so intense they result in genuine cognitive impairment. The circumstances of war, for example, can seriously degrade one's cognitive competences (Doris and Murphy 2007). However, the mistakes we are discussing here are not like this. In them, there seems to be a clear disproportion between the modest situational input and the insensitivity to moral considerations exhibited in the mistake – just to compare, whereas in the Mathews and Cannon study, noise level in high-noise conditions went up to 85db, a single gunshot may produce a sound over 160db. And it is this disproportion, at least in part, which seems to preclude the mistake in the cases considered from being excusable due to impairment.[12]

Of course, situational factors can also induce forms of temporary impairment that fall short of cognitive degradation. Despite her best efforts, a competent student might choke under pressure and, thus, be excused for bombing an exam in which she would otherwise perform aptly (Baumeister 1984; Beilock 2007). But, without any further evidence, to model the effect of noise discussed here along these lines would seem too radical. Levels of ambience noise in New York City's subway platforms, for instance, routinely cross the 85db level. Yet one would be hard-pressed to conclude on these grounds that many of the four million weekday subway riders are temporarily impaired.[13]

[12]For discussion of the extent to which situational factors, in general, can actually impede pro-social behavior, refer to the references given in parenthesis (Doris 2002, pp. 128–153; Nelkin 2005, pp. 193–194; Vargas 2013; Brink 2013).

[13]For data of noise level in NYC transportation system, refer to the references given in parenthesis (Neizel et al. 2009). Díaz and Pedrero (2006) measured sound exposure in different locations in Madrid, several of which presented averaged continuous sound levels over 85db: nightclub, soccer pitch, musical theater, primary school (exit door), and carwash.

Consider, on the other hand, *ignorance*. Certainly, there might be cases where external factors make a situation ambiguous and, thus, difficult to know whether one is required to help or not. Group effects, for instance, are perhaps explained by the fact that one takes the non-responsive attitude of other people as evidence that one's help is not needed. But clearly not all cases are ambiguous. In Matthews and Canon second study, for example, the pedestrian in distress was evidently alone, had a shoulder-to-wrist cast, and was visibly unable to collect by himself the books scattered on the ground.

Obviously, any situation in which a person behaves poorly by not realizing what is morally required at the time involves some kind of ignorance. In so far as the question whether to help never occurred to you, it is true in some sense that you did not know that you had to help there. But treating this kind of ignorance as exculpatory would be a stretch, for it does not involve the unavailability of information, or the inability to gather it. Indeed, at the time all the information necessary to make the right call was available to you and, as a competent moral agent, you could and should have inferred from this information that your help was needed.

Death by Hyperthermia

We now turn to a different kind of moral performance mistake that concerns what we earlier referred to as reasons-reactivity. The literature on human performance and human factors engineering contains a wealth of examples suggesting that many of the mistakes people make are not a reflection of deep seated attitudes in them but are rather due to small lapses of concentration and memory. Interestingly, these *slips* do not happen randomly but come in systematic patterns, which suggests that they are not isolated glitches but rather mistakes in the life of altogether normal human agents (Norman 1981; Reason and Mycielska 1982; Amaya 2013, Amaya in preparation).

Every summer in the USA, there are on average 30 reported cases of children who die of hyperthermia after being inadvertently left in the backseat of a car (McLaren et al. 2005; Weingarten 2009). In comparison to the top three causes of unintentional death of children in the country – motor vehicle accidents, drowning, and burns – the rate of deaths by hyperthermia pales. Yet, given that in at least 19 out of 50 states there are laws regarding unattended children in vehicles, 556 deaths since 1998 is by all means a grim figure.[14]

[14]Sher (2009) discusses a hypothetical case, "hot dog," that looks like the performance mistake exemplified by these hyperthermia cases. However, as he constructs his example (and other cases he discusses), the mistake is meant to illustrate a different kind of failure—one in which the mistake reflects psychological states constitutive of the agent's individual character. Even if Sher's interpretation of his hypothetical case is accepted, it is not clear that it applies generally to the real cases discussed here.

How is this *remotely* possible? Perhaps, some parents simply do not care enough about their children, or care too much about their busy lives. But, as always, if one looks at the specifics, things are less clear. Sure, some adults are simply thoughtless: They use the backseat of their car as substitutes for day cares. Some of them have deep problems managing their lives. In one instance, a drunk parent drove home, went into the house, passed out, and left the child in the car overnight. These, however, are just some of the cases: Devoted and competent parents are also touched by this tragedy (Collins 2006; Weingarten 2009). And even though they seem responsible for the death of their children, their mistakes do not seem traceable to a moral defect in them and, hence, a candidate for the *positive* condition.

Rather, a common thread behind the stories involves a change in habitual routines. During the week, you and your partner take turns dropping the child at the day care. One a given morning, however, you switch the usual schedule – your partner has an early meeting – so you seat the child in your car before leaving home. Minutes later, however, instead of taking the freeway exit for the daycare, you head straight to work. Your child is quiet. Children tend to fall asleep in a moving car.

Slips similar to these are common in everyday life. In a now classic study, Reason (1984) asked participants to keep a diary where they would record the slips they made during 1 week, indicating what they intended to do at the time, what they wound up doing, the circumstances in which it happened. At the end of the week, Reason had an inventory of 192 slips, a list with items perhaps too prosaic to deserve much attention, except that many of them shared a similar structure with genuinely catastrophic slips: "I meant to get my wallet from the bedroom. Instead, I wound the bedside clock and came down again without the wallet." As in the parental slip, in these cases, the person sets to act with an intention to do something (e.g., fetch the wallet). Yet, in the course of doing it, she gets distracted, a well-rehearsed routine (e.g., winding the bedside clock) kicks in, and she winds up derailed midway.

Diary studies raise a host of concerns; people have considerable difficulty in accurately reporting on themselves. But the general trend noticed above is one that has been observed in subsequent diary studies and in many "accident" reports collected for insurance and legal purposes.[15] When people fail to monitor their performance adequately, their behavior will automatically tend to follow well-rehearsed routines consistent with their immediate surroundings and their general know-how. As a consequence, what they wind up doing is not necessarily in line with what they intended to do, or the reasons that first motivated them to act (Reason 1990, p. 184; Amaya in preparation).

Thus, a slip constitues a further kind of performance mistake. It is in this case an *executive* kind of mistake. Here the person recognizes what she needs to do. The parent, say, recognizes that the child needs to be taken care of, carefully buckles her in the safety seat in the back, and cautiously drives out to the day care. The problem

[15]For a discussion of possible pitfalls in diary studies and self-reports of slips, refer to the references given in parenthesis (Morris 1984; Reason 1993). is failing to follow through, to execute the full plan of action. It is a matter of the agents not reacting appropriately to reasons involving the well-being of the child that she already has recognized as germane.

Think back to Fischer and Ravizza's notion of *reasons-reactivity*. According to them, in addition to the recognition of reasons, reasons-responsiveness requires *weak reactivity*. It requires, at least, that one acts on a mechanism that would function differently if the right sort of incentives were in place. Thus stated, the requirement is nicely met in the akratic case: If you were offered a $1,000 dollars to not eat the cake and stick to your diet, you will likely forgo the temptation. The case of the parental slip, however, is different. In it, all the incentives that would otherwise motivate the parent to act differently are already in place; it is not as though the parent values getting his workday off to an early start more than the life of his child, and it is unlikely that increasing the penalty for the mistake would help prevent it by increasing the cost of ending one's child's life.[16] What happens, instead, is that he acts on a habitual routine and habits tend to become somewhat rigid, which means that they need not track how moral considerations align in specific situations. That is, they are mechanisms that can guide behavior without reacting to the moral reasons that the agent accepts.

It bears repeating what we previously said regarding situational influences. In some sense, saying that the mistake is a slip functions as an excuse: It serves to signal lack of bad will, absence of intent, etc. But this is not quite yet to exculpate. For accepting that the mistake is not in the purview of the *positive* condition does not remove it altogether from the purview of practices associated with the attribution of moral responsibility. The *negative* condition, in other words, does not apply either: It is still a case of wrongdoing where some blame-related reactive attitudes seem fitting.

Again, think about the standard excuses. To begin, observe that invoking *duress* here would not work. Slips, we know, are more prevalent in situations of extreme stress, for example, an emergency in an airplane cockpit (Broadbent et al. 1986; Reason 1988). Yet, even though parenting a young child could be stressful, it does not seem that parents who make these slips are under significantly more stress than the many parents to which the tragedy never happens. Stress might mitigate; it does not exculpate.

It would seem that *ignorance* is a bit more promising. Obviously, it would not be normative ignorance: The parent knows what good parenting requires. Nor, strictly speaking, would it be factual ignorance, for the parent knows all the facts necessary to see the wrongness of his behavior. But perhaps, there still is room for some kind of epistemic mistake that makes the slip excusable. The parent, after all, does not

[16]In fact, even though in the US system, judges are generally moved by the parents suffering to give lenient sentences, there are a significant number of cases in which parents receive extremely harsh punishments: 15 years to life prison sentences or spending one day in jail on the child's birthday for 7 years. For an empirical study of the treatment of hyperthermia cases in the US judicial system from 1998 to 2003, see Collins (2006).

knowingly leave the child in the back of the car (if he knew it, he would not have done it).

The problem here is that it is not obvious what kind of epistemic mistake this could be. Notice, first, that false belief is not a good candidate. True, the parent's omission would seem more reasonable, say, if at some point, he would have come to believe falsely that the child was not in the car, or that he had already dropped her at the day care. However, given the explanation of the slip provided above, attributing the false belief to the parent to explain the mistake seems redundant (and perhaps an ad hoc move motivated only to get the *negative* condition right). The parent gets distracted, a habitual routine kicks in, and he winds up driving straight to work. The question that the putative false belief is supposed to answer, namely, what were the whereabouts of the child, never even comes up.[17]

To make this clear, distinguish mistakes that happen because what one knows fails to shape one's behavior from those in which one omits doing something due to the belief that that thing no longer needs to be done. Once the distinction is in place, the slip looks more like a case of the former, not the latter kind. The parent's belief that the child is in the back of the car at some point becomes inactive: The parent ceases to attend to it. But this is not to say that the parent comes to form a false belief about where the child is.

Now, it is true that this kind of epistemic failure sometimes excuses. Plausibly, one could be excused for not fulfilling a promise made years ago, if one temporarily forgets it. And one might also be excused if, despite trying really hard, being in a tip-of-the-tongue state, one cannot recall the name of the person with whom one is conversing. Notice, however, that the slip is unlike either of these cases in which one is excused for not acting in accordance with what one knows. The parent does not make the mistake because he fails to recall an event of a distant past, or because he tries without success to remember where his child is. In fact, it was well within his competence to bring to mind whatever he needed to have present at the time. Before the tragic day, he effortlessly did it several mornings a week.

Finally, it is worth asking to what extent the slips considered so far are *accidents*. Here, the point is a bit less straightforward. For, on the one hand, being the result of performance mistakes, slips are not committed on purpose and fall somewhat short of being instances of self-governance. Yet, on the other hand, the agent seems to have sufficient control of the actions that take place when the slip happens. The parent's drive is not a tick or stumble. He drives to work the way he does it on any given day in which his partner (not him) is on daycare duty.

To appreciate why considerations of accidentality might not be an issue here, contrast slips mistakes with paradigmatic episodes of sheer bad luck. Part of what makes the phenomenon of moral luck so hard to accommodate is that the distinction between, say, the unlucky driver who hits a pedestrian and the lucky driver who

[17]Unfortunately, in some cases, the slip does result in the person having a false belief. Having spent all day at work, some parents drive to the day care in the afternoon to pick up their child, not having realized their slip. But as an explanation of how the mistake first came about, attributing the false belief clearly gets the order of things wrong.

does not is not one that is traceable to the state of mind of the drivers (Nagel 1976; Williams 1976). But in the present case, the state of mind makes all the difference.[18] You knew all you needed to know in order to prevent the tragedy. But you left the child behind, because you were not keeping track of where she was.

This is not to say, of course, especially with catastrophic slips, that there is not something unlucky about them. It is surely a sad set of coincidences that children fall asleep in moving cars, that cars warm up so quickly, and that passers-by tend not to look at the interior of parked cars. But, in the end, it is not clear that such factors, which are admittedly beyond one's control, make the relevant difference. Would you cease to be responsible for leaving your child behind if some stranger were to break into your car and rescue her?

Conclusion

Performance mistakes do not result from a moral defect in their agents. And many of them do not occur under circumstances that make them excusable. Yet, there seem to be good reasons to hold them responsible for them. These kinds of cases are, therefore, a challenge to accounts of responsibility framed in terms of the *positive* and *negative* conditions stated at the beginning of this chapter. That is, they seem to challenge picture of responsibility and blame circumscribed by agentic moral qualities and excusability.

Again, it looks like something has to go. We might (1) argue that moral performance mistakes meet the positive and negative platitudes, or (2) jettison the positive and negative platitudes from our account of responsibility. Neither option is appetizing. Given the centrality of the platitudes in traditional and contemporary theories of moral responsibility, (2) is radically revisionary. And given what we know about the psychological mechanisms underlying the performance mistakes described here, (1) seems implausible.

There is, however, another solution, one that requires neither giving up the appearances nor giving up the platitudes. According to it, performance mistakes should be viewed, not as straightforward counter-examples to existing accounts that

[18]Here we refer to the kind of luck that is normally described as resultant luck (Nagel 1979; Nelkin 2013). Some philosophical accounts of luck, formulated in terms of chanciness, might seem applicable here: Roughly, a chancy event is one that fails to occur in a large enough number of possible worlds obtainable by making a small change in the actual world (Pritchard 2005; Coffman 2007, p. 390). Even assuming the correctness of this kind of approach to common instances of luck (see Lackey 2008 for discussion), it is questionable whether chanciness *thus understood* excuses. An agent might introduce small changes in counterfactual scenarios and that may very well mean the difference between the agent being or not being blameworthy. The parent, for instance, could put his briefcase in the backseat, which will "remind" him that his child is still in the car before anything happens to her. Of course, things might be different in relation to other kinds or accounts of luck. Levy (2011), for instance, argues that it is a matter of (constitutive) luck whether and what kind of moral considerations cross your mind at the time of any action. But notice that he advances this claim to defend his general skepticism about human beings ever being responsible.

emphasize moral qualities and excusability, but as evidence that there are several notions in the moral responsibility "neighborhood" and that existing theories capture only some of them. Performance mistakes would, thus, fall under the ambit of a notion that, while in "the responsibility family," does not require the positive and negative platitudes be met for its application.[19]

The distinction, perhaps, can be made in terms of answerability vs. accountability – but beware that these terms has been used slightly differently by others (Watson 1996; Shoemaker 2011). Answerability, on the proposed view, would mark the positive relation between a person's behavior and her qualities as a moral agent. Accountability, on the other hand, would mark the relation that the person bears to those performance mistakes illustrated here, where the violations of moral expectations are brought about by a combination of the circumstances of her action and the dynamics of the cognitive and executive capacities than agents normally rely on.

From the perspective adopted here, accountability without answerability would be a form of moral responsibility. Even though it is not dependent on agentic appraisal, it goes further than a mere negative assessment of behavior. It reflects the fact that competent moral agents are bound by reasonable expectations; that, in the absence of excusing conditions, violations of these expectations are disapproved; and that the disapproval is fittingly expressed in attitudes of blame and guilt. The difference would be that, because the violations are not traceable to anything morally deficient in their agents, recovering from the mistakes does *not* require sanction or punishment.[20]

Free Will and Experimental Philosophy: An Intervention

Abstract

This chapter reviews and then criticizes the dominant approach that experimental philosophers have adopted in their studies on free will and moral responsibility. Section "Experimental Philosophy and Free Will" reviews the experimental literature and the shared approach: probing for intuitions about the so-called compatibility question, whether free will is compatible with causal determinism. Section "The Intervention" argues that this experimental focus on the compatibility question is fundamentally misguided. The critique develops in the form of a dialogue: a staged "intervention" for an experimental philosopher who works on free will. The chapter concludes with some thoughts about how the literature can move in a more fruitful direction.

Introduction

Though not an experimental philosopher myself, I have always been a supporter of the movement and have had little patience the hostility that has too often been directed its way. The most common and tiresome objection to experimental

philosophy – I do not care about people's *intuitions* about [problem X], I am searching for the *truth* about X" – is especially misguided when applied to the problem of free will and moral responsibility, since virtually all philosophical theories on this topic – both compatibilist and incompatibilist – rely on appeals to intuition. The arguments in these theories typically operate under the assumption that we have certain intuitions about crucial cases or premises and go on to draw substantive philosophical conclusions on that basis. Experimental methods can shed light on (a) the degree to which these intuitions are shared by members of a larger community, and (b) the psychological mechanisms underlying that underlie the intuitions. Thus, experimental philosophy can help us understand the "truth" about free will and moral responsibility in ways that complement more traditional "armchair" analysis.

The general question, then, of whether experimental philosophy can make important contributions to this topic has an obvious answer. Yes, it can.[1] But has it? In recent years, I have become quite critical of the particular approach that experimental philosophers have adopted in their investigations.[2] My fear is that the approach has become entrenched – "industry standard" as one experimental philosopher has put it – which makes it harder to abandon in spite of its serious flaws. Even worse, these flaws play into the hands of the movement's critics. If my analysis is correct, experimental philosophers are testing for intuitions that the critics are *correct* not to "care" about, because those intuitions do not shed light on the truth of existing philosophical theories. As someone who sees enormous potential in its tools and methods, I find this deeply troubling. So rather than join the chorus of X-phi bashers, I have decided to do what all friends should when someone close to them engages in self-destructive behavior: stage an intervention. This intervention, in the form of a dialogue, will take place in section "The Intervention". Before that, I will summarize some foundational studies and then outline the shared approach that I find so problematic.

Experimental Philosophy and Free Will

For reasons not clearly understood by anyone, philosophers have focused most of their attention on the so-called compatibility question, the question of whether free will and moral responsibility are compatible with the truth of causal determinism. Unsurprisingly (but disappointingly), experimentalists have followed suit. Beginning with Nahmias, Morris, Nadelhoffer, and Turner's (2006) seminal studies, philosophers have attempted to directly probe folk intuitions on the compatibility question. Nahmias and colleagues presented participants with a series of

[1]See my "In Memoriam: The X-Phi Debate" on why there is no reasonable debate over this general question.

[2]See Sommers (2010, 2012) for two examples.

vignettes in which agents perform an act of wrongdoing in a deterministic world. Participants were then asked whether the agents acted of their own free will and whether they are blameworthy for the act. In each of these scenarios, a majority of the participants gave compatibilist answers to both questions. In one scenario, for example, an agent robs a bank in a determined world and 76 % of the participants judged the agent acted of his own free will and 83 % responded that he was morally blameworthy. Nahmias and colleagues received complementary results for the praiseworthy and morally neutral scenarios as well. According to the authors, these results cast doubt on the claims of philosophers, such as Robert Kane and Galen Strawson, that ordinary people – referred to (somewhat unfortunately) as "the folk" in X-Phi literature – are "natural incompatibilists."

In their influential paper, Nichols and Knobe (2007) use a similar approach to explain the asymmetry between incompatibilist claims about folk intuitions and the experimental results in the studies by Nahmias et al. They hypothesize that in philosophy seminars, when considering the compatibility question abstractly, we tend to have incompatibilist intuitions. But in concrete cases that trigger emotional responses, our intuitions become more compatibilist. To test this hypothesis, Nichols and Knobe describe two universes to their participants, a deterministic universe (Universe A) in which everything including human decision-making is completely caused by events tracing all the way back to the beginning of the universe, and the other (Universe B) where everything *with the exception* of human decisions is completely caused by past events. The key difference, according to the scenarios:

> is that in Universe A every decision is completely caused by what happened before the decision—given the past, each decision *has to happen* the way that it does. By contrast, in Universe B, decisions are not completely caused by the past, and each human decision *does **not** have to happen* the way that it does. (p. 669)

Participants were then divided into a concrete high affect condition and an abstract low affect condition. In the low affect condition, participants were simply asked if people could be fully morally responsible for their actions in this deterministic universe. Here, a large majority (86 %) of the participants answered "no." The high affect condition describes a man named Bill who burns down his house, killing his wife and three children, so that he can be with his secretary. Participants are then asked if Bill is fully morally responsible for his behavior. In this condition, 72 % of the participants answer "yes." Nichols and Knobe offer these results as an explanation for the intractability of the free will problem. When we consider the problem abstractly, one set of cognitive processes lead us to the conclusion that determinism is incompatible with free and responsible action. But cases like Bill trigger a different set of processes that dispose us to assign blame and responsibility for terrible crimes and worry less about how they were caused.

A related factor that may affect our intuitions on freedom and responsibility is *psychological distance*: the distance (either in space or time) between participants and the event or object and events they are considering. Weigel (2011) asked participants to imagine hearing a lecture about a deterministic universe, and

were then asked if a murderer in this universe acted freely. Some participants were assigned to a condition in which the lecture on determinism was taking place in a few days. Others were assigned to a condition in which the lecture took place in a few years. This seemingly small manipulation had a significant effect. The results showed that participants were less inclined to say that this man freely decided to kill his family when they imagined hearing about it at a more distant time. Research on psychological distance suggests that greater distance triggers cognitive processes that deal with questions more abstractly, so these results lend support to the view that our conflicting intuitions on free will are the product of different cognitive processes.[3]

Feltz and Cokely (2009) also adopt this general framework in their studies, but add an interesting twist: The authors investigate whether personality differences can affect intuitions on free will. Specifically, Feltz and Cokely predicted that participants who were high in personality trait extroversion would be more likely to attribute free will and moral responsibility to a murderer in the deterministic scenario. Rather remarkably, the results showed a significant correlation between extroversion and a willingness to attribute free will and responsibility for determined behavior. These results suggest yet another reason for why philosophical reflection and debate alone have not led to more universal agreement about the free will problem.

In the above studies, participants are asked to imagine a world where human behavior is caused deterministically, but they are given no detail about the nature of the causation. Several studies have shown, however, that the *type* of causal explanation can influence free will and responsibility judgments. Monterosso et al. (2005) found that participants were more likely to exonerate agents from responsibility for crimes when the explanation for their action was physiological (e.g., a chemical imbalance) in nature rather than experiential (e.g., abusive parents). Nahmias, Coates, and Kvaran (2007) and Nahmias and Murray (2010) separated participants into two conditions. In the first, agents' decision-making is described "in terms of neuroscientific, mechanistic processes"; in the second, decision-making is described "in terms of psychological, intentional processes ("psych scenarios")". They found that participants in both abstract and concrete cases regarded the neuroscientific descriptions of decision-making as more threatening to free will and responsibility than psychological descriptions.

[3]An experiment by Roskies and Nichols (2008), although not designed explicitly to test the effect of psychological distance, supplies further evidence of its influence The authors predicted that intuitions about free will and moral responsibility would be sensitive to whether deterministic scenarios are described as *actual*, in our world, or merely *possible* (true in some other possible world). In the "alternate condition," the description of determinism is the same, except that the universe the subjects are asked to consider is not our own. The subjects then respond to similar probes about free will and moral responsibility in this alternate universe. Consistent with the authors' hypothesis, the assignments of free will and moral responsibility were significantly higher in the actual condition than in the alternate condition.

Nahmias and colleagues offer these results as evidence for an “error theory” for incompatibilist intuitions. The results, they argue, show that participants are prone to confuse determinism with *fatalism*, the view that our conscious desires and deliberations does not causally influence our behavior and destiny. But this is an error – determinism does not entail that our conscious deliberations do not cause our behavior, only that the deliberations are themselves determined by previous causal factors. The authors conclude that folk intuitions might be more unified in favor of the compatibilist view that we can be free and responsible as long as our actions are determined in the right way, i.e., through our deliberation.

Most of the other experimental work on free will and moral responsibility has employed this same basic approach, which can be outlined as follows.

1. **Select the variable to be manipulated.** Examples described above are concrete versus abstract cases, affect-laden versus affect- neutral cases, psychological distance, temperament, and type of causation. Other studies have manipulated the culture of the participant (Sarkissian et al. 2010), examined patients with emotional deficits (Cova et al. 2012), and the world in which the wrong-doing in the vignette takes place (our world or a different one) (Roskies and Nichols (2008)).
2. **Describe a world in which all human action is determined.**[4] With a few important exceptions, most studies have adopted the description provide by Nichols and Knobe (2007)[5]. Participants are asked to imagine that determinism is true, or asked hypothetical questions about what would be true in such a world.
3. **Probe for intuitions about free will and moral responsibility.** Finally, the participants are asked whether agents can be free or morally responsible for their behavior in this world. The behavior differs depending on the study and the manipulation, but typically the author will describe an example of wrongdoing in the determined world and then ask whether the agents acted of their free will and can justly be held morally responsible for this action.

With several notable exceptions, this is the general approach that experimental philosophers have adopted in their investigations into this topic.[6] As noted above, I believe this approach has several flaws that are serious enough to make an intervention necessary.

[4]Monterrosso et al. (2005), to their credit, do not discuss determinism. Instead, they vary the percentages of people with a particular condition—psychological or physiological—who go on to commit crimes.

[5]Eddy Nahmias objects that the “had to happen” language in this description begs the question against compatibilist analyses of choice. His studies do not employ this description.

[6]See Sripada (2012) and Feltz (2012) for examples of studies that stray from this approach, and thus are not vulnerable to the central criticism of this chapter.

The Intervention

The following is a transcript of a conversation with an Experimental Philosopher Who Works on Free Will and Moral Responsibility (acronym: ETHAN). Three friends of the experimental philosopher—Emma, Sarah, and Maynard—*have asked Ethan to come for a brief "healing" session to get him to address some recurring problem with his work.*

Emma: The first thing I want to make absolutely clear is that we're here to help you. Everyone here is in your corner. We're not here to be dismissive, to tell you that your projects are not "really philosophy" or that they have no value.

Maynard: Not that you deserve all the fawning media attention you get either, but. . . .

Sarah: Stop that. We're here to help Ethan, not lash out.

Ethan: What exactly are all of you talking about?

Emma: We all got together and agreed that we needed to have, well, a conversation with you. We think you've been in a bit of a self-destructive spiral recently. We know you can pull yourself out of it, but first you have to recognize what's happening. We don't want things to get to a point where you've lost all everything and you're just handing out flyers in Washington Square park like a. . .

Ethan: Isn't that how this experimental philosophy thing got started?

Emma: Ok, bad example. We don't want him descending to a point where he's camped out in the woods on the outskirts of some university just. . .

Sarah: Again. . .

Emma: Fine! Let's just get this over with, ok?

Ethan: My sentiments exactly.

Sarah: Let's begin with the elephant in the room, the biggest problem of all, the one that's plagued your work from the beginning, the days of Nahmias, Nadelhoffer, Morris, and Turner. A lot of the other problems stem from this one. Now Ethan—what is the whole justification for probing the "folks" about their intuitions?

Ethan: The folk.

Sarah: Whatever. Why is probing for intuitions important in the first place?

Ethan: You know the answer to that. Philosophers appeal to intuitions all the time, that's how they defend their theories of free will. They appeal to intuitions in their arguments. I say this at the beginning of practically every paper I've published.

Emma: And rightly so, good. But you can't just probe for any intuitions you want, right? Which intuitions would you want to probe?

Ethan: Intuitions about free will and responsibility. Obviously.

Maynard: So you just want their random fragmented thoughts about free will?

Ethan: You know what I mean. The intuitions that are at center of the debate.

Sarah: Right. And even more specifically, wouldn't you want to test for the same intuitions that the philosophers are appealing to in their theories and arguments?

Ethan: Of course, that's obvious.

Maynard: If it's so obvious why aren't you doing it?

Ethan: What do you mean? I am doing it.

Maynard: No you're not. Let me ask you something—how many, say, incompatibilist arguments are there that go like this?

1. If determinism is true, then intuitively there is no such thing as free will.
2. Therefore, determinism is incompatible with free will.

Does that sound like a good argument to you? Or would that be a just little question-begging?

Ethan: Well, that would be question-begging. Although Robert Kane and Galen Strawson do say that people start out as naturalists incompatibilists and have to be talked out of it by the clever arguments of compatibilists.

Maynard: We know, trust us. You quote the same damn passages in all your papers. And you know where every one of those passages come from? Introductions. They aren't part of any theory, not part of any argument. They add nothing of substance. They're throwaway lines. *They play no role in incompatibilist arguments*, they're just there to set the mood. So let me ask you again: is that what you think is so important to test? Intuitions about introductory throwaway lines in incompatibilist books and articles?

Ethan: I'm not sure I fully understand....

Emma: What he's trying to say is that you're testing intuitions on the wrong question. You're probing intuitions on the compatibility question itself. You're testing intuitions about the *conclusions* of compatibilist and incompatibilist arguments. But philosophers don't appeal to intuitions about conclusions. They appeal to intuitions about the *premises* of their arguments, intuitions about cases or narrower principles like transfer principles or PAP principles.[7]

Ethan: Ok, right, I see. You think that people's intuitions about those principles or cases might be different than their intuitions about the compatibility question itself.

Sarah: Exactly.

Ethan: That's an interesting hypothesis, you should test that.

Maynard: Here's an idea. How about after someone makes an objection to a study or a whole series of studies, you don't just sidestep it by telling them they should test it? You know what *real* scientists never say when people raise objections to their studies? "That's an interesting hypothesis, you should test that." You want to know why they don't say that? Because they know that other people have their own lives, their own labs, their own careers, and they're not going to drop everything just because of the problems with another psychologist's experiment.

[7]The transfer of non-responsibility principle, roughly speaking, is that we cannot be morally responsible for an act if we are not morally responsible for any of the determining factors of that act. (The non-responsibility for the determining factors "transfers" to the act itself). See Fischer and Ravizza (1998) for a more precise formulation. The Principle of Alternate Possibilities (PAP) is the principle that an agent can only be morally responsible for an action if they had the capacity to act otherwise.

Ethan: But Josh Knobe says that all the time.

Sarah: Look, Ethan. I know this is difficult. But Joshua Knobe, much as we all admire him and love him, important and influential as he is, Josh Knobe is not God.

Ethan: I know that.

Maynard: Say it then. Josh Knobe is not God.

Ethan: I just said it.

Emma: (gently) No you didn't.

Ethan: (fidgeting uncomfortably) Ok, fine. He's not.

Maynard: Not what?

Ethan: (more fidgeting). Not God.

Maynard: Who's not God.

Ethan: Josh Knobe, OK? Josh Knobe is not God. Satisfied?

Maynard: The point is that this a glaring flaw with *your* experiments, *your* whole way of approaching this topic. *We* are working on other things have other commitments.

Emma: This is a serious problem, Ethan. You're not asking the right question. And it's plaguing so much of your work these days.

Sarah: It really is—at the very least, four out of every five X-phi studies use this model. There is so much creativity and potential in experimental philosophy, so many fascinating ideas, but we have no idea what to make of the results because of the flaws of the model. Look at this study that's just coming out by Florian Cova and colleagues (2012): "Judgments about Moral Responsibility and Determinism in Patients with Behavioural Variant of Frontotemporal Dementia: Still Compatibilists." What a cool idea, right? Testing patients with emotional deficits. We can learn so much—there are so many potential implications for Strawsonian approaches to moral responsibility to name just one. But what is he doing in the study? He's giving these patients the same questions that Nichols and Knobe gave in their original *Nous* article—questions that test the *conclusions* of arguments. And based on their responses he concludes that the patients are "still compatibilists." But you can't say that they're still compatibilists unless you ask the right question! You're wasting so many golden opportunities.

Ethan: Look, these questions are industry standard now.

Emma (to Sarah): Avoidance.

Maynard: Are you listening to us? That's our whole point: the industry standard is seriously screwed. And anyway, Nichols and Knobe came out in 2007 for Christ sake. The Nahmias et al. papers came out in 2006. How much of a standard can there be in a few years?

Emma: You need to change the industry standard, or else every other future paper will have this exact same problem that undermines everything you're trying to do.

Ethan: Ok then how about the recent Chandra Sripada (2012) article that probes for intuitions about manipulation cases and then for intuitions about whether manipulated agents are acting from their 'deep self.'

Emma: Right, good! That's exactly the kind of approach that you need to adopt—because it's testing *premises* of real philosophical arguments! But that paper is the exception. It strays from the "industry standard" and it should.

Sarah: Let me point out something else. The original classic X-phi study—the famous Josh Knobe in Washington Square park experiment with the CEO and the environment—that worked precisely because it was testing for the right intuitions (See Knobe 2006). Intuitions about a particular case. No determinism, no ambiguous words. Did the CEO intend to help or hurt the environment? That's it. Now that's a model of the kind of thing you need to be doing.

Emma: And this leads us to the second problem we think you need to face up to.

Ethan: Christ, what now?

Emma: These concepts that you're asking about in the studies are far too complex and ambiguous for non-philosophers. They can be interpreted in so many different ways. This means there's too noise in your experiments even if you were probing for the right intuitions.

Ethan: Can you be just a little more specific?

Sarah: Well, I hate to pick on Nichols and Knobe, but they can handle it. Let's go back to their study. They give their participants a description of a determined universe, we talked about the problems with that already. But then they ask their participants: Can an agent, or can Bill, be "fully morally responsible" for his actions? Now, think about that: "fully morally responsible," what is that supposed to–

Maynard: I've worked in this field my whole career and I have no clue what the hell that means.

Emma: The point is that 'fully morally responsible' can be interpreted in a lot of different ways. I mean: is anyone ever *fully* morally responsible? External factors play *some* role in every action, right? Nobody disagrees with that.

Ethan: So how would you put it then?

Sarah: Good question. To be honest, every time I teach this topic in an intro course it takes me at least 15 or 20 minutes to nail down the sense of moral responsibility that's at the center of the debate.

Ethan: What sense is that?

Sarah: Moral desert, deserving blame or punishment independent of the consequences.

Ethan: Fine but you can't say 'moral desert.'

Emma: That's right, you can't. That's a meaningless term to a 19 year old non-philosophy major. And even philosophers disagree about how to analyze moral desert.

Sarah: And when I bring up responsibility in my class, we've already discussed non-consequentialism so I can use terms and concepts that wouldn't work for your surveys of non-philosophers. That's why I can get the concept across in only 15 or 20 minutes. But "non-consequentialist desert" is certainly not what most people think of when they hear "moral responsibility" if they think about it at all.

Emma: It's a really tough concept, right? But as philosophers who work on this issue, *we* know what we mean by morally responsibility (for the most part), so we've forgotten all the different ways that people interpret it and how confusing it can be.

Ethan: Ok, so what about 'blameworthy' and 'praiseworthy'?

Emma: I don't think so. Those are still philosopher's terms. People don't use that language outside of a class or maybe a courtroom.

Maynard: Nichols and Knobe is not even the worst example. How about Roskies and Nichols asking if people "*should be morally blamed* for their actions" in a determined universe. That's confusing on so many levels.

Ethan: Now hold on. That paper was published in the *Journal of Philosophy*!

Maynard: Oh my god you're right! It must be flawless then. Can you stop avoiding the issue? First of all, what do they mean by 'morally blamed'—have you ever heard anyone use that term in your life? Even worse, someone could think people should be blamed for consequentialist reasons even if they don't deserve it.

Sarah: And this is our point. It's one thing to avoid getting bogged down by trivial philosophical distinctions. We're all in favor of that. We're not fastidious word-choosers, we don't get aroused by conceptual analysis. But it's another thing to play so fast and loose with terms that you have no idea what your participants mean by their judgments. That's exactly the kind of noise you have to minimize in a study.

Ethan: Let me tell you something: it's pretty easy to just sit there in your armchair and criticize our terminology and our work. But I haven't heard you suggest any better options.

Maynard: Don't play the martyr with us. It's not our job to write your studies for you. The problem with you X-Phi people is that you get too much unfair criticism, all those hostile strawman objections from philosophers who feel threatened by experimental philosophy. So now you have a bunker mentality. You can't see that there might be legitimate serious problems out there.

Sarah: Ethan, we understand that it's tough getting that language right. I've thought about this a lot and I have no idea how to phrase those questions. It's a serious difficulty. Maybe you need to get a little more clever and oblique. Maybe you can do some behavioral studies where someone gets punished at a cost for no other reason than they deserve it.

Maynard: And keep it as close to real life as possible. For the love of God, no more planet Erta scenarios or hypothetical worlds where alien scientists have developed supercomputers to detect neuronal activity and predict everything that will happen. Who the hell knows what are intuitions mean when they're completely divorced from reality.

Ethan: Philosophers use wacked out thought experiments all the time! You can't blame *that* on me.

Maynard: Philosophers hold their big job meeting between Christmas and New Years in cold weather cities. Does that make it right? Moral responsibility is a *human* phenomenon. Our intuitions respond to actual things that happen to us, not to ludicrous science fiction fairy tales. We probably learn something from probing judgments about alien worlds and whacked out fantasies about evil neurosurgeons, but nothing resembling what we want to learn.

Ethan: I actually agree with that. But look, this is a new field. We're learning on the fly. How do you think that we're going to make any progress if we don't try new things?

Emma: I'm so glad to hear you say that, Ethan. What it shows is that you're starting to recognize the flaws in your approach. You're making progress.

Ethan: Great, thanks. If only you didn't sound so patronizing. . .

Maynard: You want less patronizing? I can handle that. I have a couple things to get off my chest and I promise you it won't sound patronizing.

Sarah: Let's stick to the plan, OK? The next item on the agenda is how Ethan is starting to overreach a bit. Overstating the significance of certain results. . .

Maynard: Overreach?? Are you freaking kidding me? I want to read something to you. You wonder why you have so many hostile unsympathetic critics, right? Well here's some prime ammunition for them. All of your problems distilled in a couple pages. This is from Knobe and Nichols in the new edition of the Kane free will anthology. Let me read this to you. They're discussing a possible objection, one suggesting that different cultures might possibly have different intuitions about free will and responsibility than some college students at Florida State or wherever. And that certain intuitions in the debate may be shaped by cultural forces like the American emphasis on individual autonomy. You want to talk about patronizing? Here's how they respond:

> We certainly agree that these [diversity claims] are very plausible hypotheses but the empirical evidence thus far has not been kind to them. In a recent study, subjects from India, Hong Kong, Colombia and the United States were all presented with the abstract condition of the experiment described above (Sarkissian, Chatterjee, De Brigard, Knobe, Nichols & Sirker forthcoming). Strikingly, the majority of subjects in all four of these cultures said that no one could be fully morally responsible in a deterministic universe, and there were no significant cross-cultural differences in people's responses. Yet ordinary people, many of whom have never thought about these questions before, seem somehow to immediately converge on one particular answer. In fact, we find this convergence even across four different cultures, with radically different religious and philosophical traditions. What could possibly explain this striking pattern of intuitions? (Knobe and Nichols 2011, p. 532)

Ethan: Right, that's an interesting result. What's the problem?

Maynard: Well, let's break this down. "The empirical evidence has thus far not been kind" to the diversity hypothesis. What does this unkind empirical evidence amount to? One study. Is there a mass of empirical evidence that suggests otherwise? Yes. Is any of it discussed? No. But OK, that evidence doesn't specifically concern the compatibility question (which is itself an obsession of philosophy in the West, but just set that aside for now). So maybe they're after something more specific. All right, let's look at the study. They give the Nichols and Knobe deterministic scenario to university students in Hong Kong, India, and Columbia. University students! They supposedly represent the essence of every culture. They then ask is it's possible for someone to be morally responsible for their behavior in that deterministic universe. We already talked about the fundamental flaw in this approach—you're testing intuitions about the conclusion of all the compatibilist and incompatibilist arguments. But set that aside too for now. Pretend that's not a problem. They're still basing this incredible conclusion—universal convergence on an ancient philosophical

problem—on *one study*. One study that gets a null result! Let me repeat that: the null result of a single study. That's the evidence that "hasn't been kind" to the diversity hypothesis. A null result—who the hell knows why you didn't get significant differences? There are so many possibilities. Could something be wrong, I don't know, with the methodology? Could that be why you didn't get significant differences? And we've talked about the problem with 'fully morally responsible' in English. What word are you using in Chinese? As far as I know, there isn't even Chinese word for moral responsibility in the sense that we're talking about.

Ethan: The Hong Kong students were fluent in English. They did the study in English.

Maynard: Great, even better! These Hong Kong students who are fluent in English are supposed represent ordinary people in a different culture with "with radically different religious and philosophical traditions." And they're supposed to interpret "fully morally responsible" just like the Americans, and just like me I guess, even though I still don't have a clue what that means. And of course, all the participants in each country are (a) university students, (b) from high SES backgrounds, and (c) of university age. These are your "striking," "deeply puzzling and mysterious" results that cry out for explanation. A null result from the judgments of university students in a second language in a study with ambiguous terminology that asks the wrong question. Do you see the problem? Do you see why people get mad at experimental philosophers?

Ethan: You seem to be taking this study personally.

Emma: I think he knows someone who wrote a book on the diversity of intuitions about moral responsibility.

Ethan: Who?

Maynard: Nobody, that's not the point, let's stick to the issue.

Sarah: We don't have problems with the study so much—well, besides the ones we've already talked about. The issue here is more with the wild claims that Knobe and Nichols are making about it. The study is, at best, an intriguing first step. It might even be suggestive if it weren't for the problem that it tests the wrong intuitions. But you have to admit: it's completely implausible to conclude that "ordinary people, many of whom have never thought about these questions before, seem somehow to immediately converge on one particular answer."

Maynard: Let's put it this way. You're always complaining about armchair philosophers who pull their claims about people's intuitions out of their you know what. But is what you're doing here any better?

Ethan: At least we're trying to test for intuitions in these other countries. That's something, isn't it?

Maynard: It's something, but it might be worse in the end than what the armchair people are doing because it's bathing itself in the haloed pretense of real empirical support.

Ethan: (Breaks down, sobbing). You're right. Oh God I see it now! I'm so so soooorrry.

Emma: Good, good... let it out.

Sarah: It's Ok, we're here for you.

Maynard: This is bullshit, right?

Ethan: (stops sobbing immediately). Yes, I figured that's what I was supposed to do. But seriously, I get the point. Can we wrap this up?

Emma: I don't know, can we? What have we learned from this so far?

Ethan: Look, if you're waiting for me to really break down and start sobbing, that's not going to happen.

Sarah: We don't expect that, we just want an acknowledgment that you understand that you have some problems and that you intend to address them. Again, we're your friends and you have our full support.

Ethan: Ok, yes, I'll try to address them.

Maynard: Address what?

Ethan: All right, fine. First, I have to stop giving scenarios with deterministic worlds, and then asking if people can be morally responsible in them.

Emma: Because?

Ethan: Because when I do that, I'm not probing for the intuitions that philosophers are appealing to in their arguments. I have to start testing for intuitions about cases and principles, and investigating the source of those intuitions.

Sarah: Exactly!

Ethan: Second, I need to nail down the sense of moral responsibility we're after. Not that you had any good ideas about the best way to do that but... that's my responsibility.

Maynard: In a different sense of the word, yes it is.

Ethan: Ha ha, you should be headlining in the Catskills. Third. I need to avoid outlandish thought experiments and bring my scenarios down to earth as much as possible. Fourth, I need to stop exaggerating the implications of the data from my studies, even though most social psychologists and cognitive scientists do that all the time.

Emma: Fair enough. But that doesn't make it right.

Ethan: No it doesn't. And fifth–

Sarah: Let me just say, Ethan, that although we've been a little harsh with you today, we are doing it out of love and respect. You've brought so much energy and excitement to our field, breathed new life into it. And we think you have the potential to significantly improve our understanding of free will and moral responsibility.

Emma: Amen. We all agree with that, right Maynard?

Maynard: (grumbling) Right. Yes.

Sarah: Continue Ethan.

Ethan: Thank you. Fifth—and most important—the next time my friends invite me to a so-called "intervention" about my work, I need to tell them to get a life and mind their own business.

Neuroanthropology

Toward a Neuroanthropology of Ethics: Introduction

Abstract

The main argument of this introductory chapter is that there is a pressing need for a neuroanthropology of ethics because the neural bases of moral agency are to be found beyond the confines of a single brain: in the coming together and interacting of a community of brains, in the shaping of the moral brain by the social field and culture, and in the workings of a neurocognitive system that evolved to absorb, reproduce, and contribute to shared worlds of meaning. This chapter shows how the papers in this section demonstrate the need for a neuroanthropology of ethics that is sensitive to context, culture, history, and diversity as well as to the relationship between universalism and particularism, scientific fact and personal experience. This chapter also outlines areas of future research in neuroethics from a neuroanthropological perspective. A neuroanthropology of ethics is well placed to unsettle long-held assumptions about ethical behavior. It also offers new ways of approaching ethical phenomena and opens up exciting new avenues of enquiry.

Anthropology and Ethics

Understanding different ethical systems and diverse forms of moral life has been at the core of anthropological enquiry. "Ethics" and "morality" have often been indistinguishable from "culture," "ideology," or "discourse," concepts used in anthropology to represent shared rules, ideas, values, beliefs, opinions, desires, and preferences. This is not surprising as society was equated with morality for a long time in anthropology, ever since Durkheim defined society as a system of moral facts (Laidlaw 2002; Zigon 2008). As a result, anthropologists have documented in their ethnographies of societies the world over the set of ideas, values, preferences, and practices that underpin local ethics. Adding to this rich history, over the past 15 years there has been renewed anthropological interest in ethics as a separate analytical field. The methodological and ontological ground of this new anthropology of ethics is the individual, but this is a relational individual who has undergone substantial socialization. An ethical subject, from this perspective, is "always of intersubjective, social and cultural tissue" (Faubion 2011, p. 120). This recentering of the object of study has allowed anthropological enquiry to move beyond questions of social regularity and control where individual moral behavior is understood as acquiescence or transgression (Laidlaw 2002; Zigon 2008). The anthropology of ethics has in particular started to consider issues having to do with how and where ethical subjectivities form; with reference to which particular set of ideas, values, preferences, and practices are these subjectivities formed; how are they expressed in ordinary, everyday social encounters; to what extent does ethical behavior manifest through the adherence to or creative transcendence of normative action; what is the role of reflexivity and habitus in the expression of ethical behavior; and to what extent individuals inhabit different ethical subjectivities (Laidlaw 2002; Zigon 2008; Lambek 2010).

A distinctively anthropological perspective has therefore much to contribute to neuroethics. An anthropological neuroethics can first and foremost draw upon anthropology's virtually inexhaustible trove of ethnographic data to test the universality of neuroethical claims; to investigate the local conditions that modulate brain responses associated with the formation of ethical values, behaviors, and predispositions; or to better understand the relationship between context and the neural correlates of ethical behaviors. An anthropological neuroethics can further draw upon anthropology's increasingly sophisticated understanding of ethical subjects (as intersubjective, as the product of socialization and enculturation, as inhabiting various ethical positions, as reproducing and transcending normative action, etc.) to guide enquiry into the neural bases of moral agency (see also ▶ Chap. 9, "The Neurobiology of Moral Cognition: Relation to Theory of Mind, Empathy, and Mind-Wandering"). But at a more fundamental level, an anthropological neuroethics is necessary for the same reason that an anthropological neuroscience is ultimately necessary: because human individuals are not pure individuals; because they cannot be more fully understood either in isolation or as an abstraction; and because they are cultural individuals, intersubjective individuals, individuals who inhabit (and contribute to) a world of meaning shared with others. The neural bases of moral agency, like the neural bases of human activity more broadly, cannot therefore be understood without reference to this anthropological individual.

Neuroanthropology and Ethics

The aforementioned anthropological neuroscience, or neuroanthropology, as a field of study interested in "the experiential and neurobiological aspects of cultural activity" (Domínguez et al. 2010, p. 140) is already in existence. In a great display of foresight, the field was first formulated over three decades ago [by a small group of scholars including Charles Laughlin (D'Aquili et al. 1979), contributor to this section], well before new and powerful technologies (including not only brain imaging but also high performance scientific computing) and analytic approaches brought about the current neuroscientific revolution. Recently, interest in neuroanthropology has been bolstered as a result of these technical innovations and by the picture of the human brain they are starting to draw, which is in better accord with evolving anthropological models of human behavior. Such a brain is plastic, plural, and highly responsive to the environments it is embedded in, including "the human body, the social field, and the longer-term, larger-scale structures that are the product of human brains yoked into cooperative [and competitive, it should be added], cumulative [but also ever changing] systems" (Lende and Downey 2012, p. 2), that is, cultural systems. A striking demonstration of the brain's responsiveness to these environments is that they account for a large proportion of the brain's structural variability, as measured by volume variation across the brain (Brun et al. 2009); in other words, these environments literally shape the brain (particularly white matter, the wiring of the brain that allows different brain areas to communicate, and the frontal cortex, which is the seat of higher cognitive functions, including executive control and reasoning). Moreover, cultural neuroscience, a field of study that has overlapping aims with neuroanthropology, has provided extensive evidence of cultural influences on brain function, all the way from perceptual judgments (Hedden et al. 2008), to attentional control (Ketay et al. 2009), emotional responses (Chiao et al. 2008), theory of mind (Kobayashi et al. 2007, 2008), self-knowledge, and self-construal (Zhu et al. 2007; Han et al. 2008; Lewis et al. 2008; Chiao et al. 2010).

In addition to cultural influences on brain structure and function, neuroanthropology is interested in questions such as how are socially shared meanings and practices represented in the brain; how does the brain appropriate and act on cultural experiences; what are the neural mechanisms that make culture possible; how did these mechanisms evolve; and how do they interact with genetically mediated neurocognitive processes and behaviors (Domínguez et al. 2010). Examples of neuroanthropological research addressing these questions include functional neuroimaging of role playing (Whitehead et al. 2009); neural encoding of basic types of social relationships (Iacoboni et al. 2004); neural substrates of the disposition to treat someone as a rational agent (Gallagher et al. 2002); sociocultural patterning of neural activity during self-reflection (Ma et al. 2012); social interaction research through simultaneous two-person brain imaging or hyperscanning (Konvalinka and Roepstorff 2012); relational coding as the principle of prefrontal cortex function as well as the basis for the sharing of experience (Domínguez et al. 2009); and differences in resting-state activity between human and chimpanzee brains (Rilling et al. 2007).

An anthropological neuroethics is clearly necessary because, as the above account implies, the neural bases of moral agency are to be found beyond the confines of a single brain, in the coming together and interacting of a community of brains; in the shaping of the moral brain by the social field and by those collective long-term, large-scale systems of ideas, values, models, preferences, and practices known as cultures; and in the workings of a neurocognitive system that evolved to absorb, reproduce, and contribute to shared worlds of meaning (Domínguez et al. 2009; Whitehead 2012).

Another aspect of neuroanthropological research of importance for neuroethics is neuroanthropology's critical, reflexive, and meta-analytic undertakings, which speak not only to the practice of neuroscience but also to the implications of neuroscientific knowledge for people's understanding of their own behavior, and to political and social uses of this knowledge (see also ▶ Chap. 33, "Historical and Ethical Perspectives of Modern Neuroimaging", and ▶ Chap. 40, " Neuroimaging Neuroethics: Introduction") (Domínguez et al. 2010; Domínguez 2012; Lende and Downey 2012). Researchers have, for example, problematized the process that leads to the generation of brain images as scientific "facts" by drawing attention to how experimental design, data gathering strategies, analysis, and interpretation of results incorporate and reinforce cultural assumptions about human nature, normality, brain function, and the relationship between experience and the brain (Dumit 2004); highlighting how components of this process are obscure to most researchers who must accept that subjects are transformed into objective brain images as if by magic, by automated, largely black boxed computerized procedures (Roepstorff 2002); and bringing to light the discursive concealing and marginalization of subjects and subjectivity in brain imaging resulting in the scientific process and its products gaining an inflated appearance of validity (Domínguez 2012). In addition, Turner (2012) has called into question the ontological status of the terminology used to describe mental and cognitive constructs and has recommended that a scientifically more useful ontology may result from ethnographic reports of such constructs across cultures. Dumit (2004) has also critically written on the social history of brain images after they leave the laboratory detailing how these images, rather than *illustrative* of "textual and quantitative proof" (Dumit 2004, p. 142) as intended in scientific papers, have come to be seen in popular magazines (see also ▶ Chap. 92, "Neuroscience, Neuroethics, and the Media"), in the eyes of policy makers, or the courtroom (see also ▶ Chap. 84, "Neuroimaging and Criminal Law"), as the *proof itself* of a normal brain, a depressed brain, or an insane brain; and as straightforward, objective, unmediated photographs of these categories. Lende and Downey (2012) have, on their part, underscored the need for neuroanthropology to study how "laboratories, government institutions, funding bodies, and professional organizations" fashion neuroscience knowledge and practice, to then "examine how the biomedical industry as well as lay people draw on this knowledge to understand and manage issues related to health and well-being" (see also ▶ Chap. 69, "Using Neuropharmaceuticals for Cognitive Enhancement: Policy and Regulatory Issues") (Lende and Downey 2012, p. 7).

Contributions in This Section

The aim of the foregoing discussion has been to show that anthropology is doubly relevant for neuroethics: not only has anthropology a solid and evolving corpus of knowledge regarding ethics and morality but also a growing body of understandings having to do with the relationship between culture and the brain. The ingredients are therefore there for a neuroanthropology of ethics. The papers in this section are a first formal contribution in this direction. In the opening paper, "The sense of justice: a neuroanthropological account," Charles Laughlin critiques the highly abstract, elaborate, hyperational, and ethnocentric view Western philosophers have of justice and proposes instead what he calls a *sense of justice* [justice, sense of] in order to better capture an attribute that intuitively seems to be shared by people everywhere. According to Laughlin, the sense of justice is inherently relational and emerges from linking a basic intuition for fairness or balance with a capacity for empathy and the experience of positive and negative affect. Laughlin argues that these component elements of the sense of justice are mediated by discrete neurophysiological mechanisms, which have precursors in other big-brained social animals. For Laughlin the sense of justice is universal, but it manifests differently depending on social structural and cultural factors. He offers examples of how the sense of justice plays out in specific contexts using ethnographic cases (including from his own fieldwork) and by showing that the sense of justice fulfills different functions in egalitarian and less stratified band and tribal societies compared to hierarchical, highly differentiated, bureaucratized societies: it is a structuring principle of social institutions among the former but becomes alienated from social procedures and juridical institutions in the latter.

In "Free will, agency, and the cultural, reflexive brain," Steve Reyna starts, like Laughlin, with a critique of Western philosophical conceptions about the will, concerned, as they have been, with a functional account of this construct but neglecting altogether its underlying substance, its structure, its materiality, and the set of mechanisms that give rise to it. Reyna identifies the brain as the structure of will and the brain's reflexivity as a key mechanism giving rise to will. By reflexivity Reyna means the brain's capacity to monitor the outer and inner milieus. Reflexivity thus understood engenders will as it constitutes a resource for finding out what is the state of the world to then figure out what to do about it. However, in the case of the human brain, action is biased by culture, which constitutes a set of understandings about the state of the world and what to do about it that are *socially shared*. The corollary is that "a culturally reflexive brain performs the functions of will." Finally, Reyna adopts a critical stance by arguing that free will (see also ▶ Chap. 13, "Neuroscience, Free Will, and Responsibility: The Current State of Play," ▶ Chap. 14, "Consciousness and Agency," ▶ Chap. 17, "Free Will and Experimental Philosophy: An Intervention," and ▶ Chap. 15, "Determinism and Its Relevance to the Free-Will Question"), understood as "unrestricted action," is inconsistent with a brain that has a definite structure defined by biology or culture or both. For Reyna, acts of will are a consequence of the brain's biological and cultural determinants and biases. He further argues that the notion of free will is often deployed as

a tool of domination by those in power, who may allocate responsibility for acts of transgression (like theft) entirely on the "free will" of those transgressing without reference to social structures (e.g., of poverty) with a causative role. Instead, Reyna advocates the use of the alternative concept of "agency" as it better incorporates such structures and explicitly articulates issues of power in the expression of will.

In the last contribution to this section, "What is normal? A historical survey and a neuroanthropological perspective," Paul Mason argues against an objective basis for the concept of normality, tracking down its historical roots, following its development, highlighting its inconsistencies, dissecting its uses and their contexts, and denouncing its abuses. Mason exposes normality as a tool of homogenization and essentialization, as a tool for obscuring the diversity of human phenomena and, as such, as an instrument of control in the hand of powerful, interested actors. Diversity is, according to Mason, not merely obscured but often made out to be degenerate. The concept of degeneracy, Mason shows, has itself been discursively maligned as part of the normalizing drive, its neutral meaning of divergence from a type being co-opted by a morality of deviance and decay. Mason reviews the effect of normality on the neurosciences where diversity in brain structure and function is reduced by transferring individual brains to a standard space; by using standardized, average results as markers of kinds of people; by generalizing the results of brain research focused on a very narrow band of the human population (largely young, university students of contemporary Western industrialized nations); and by reducing to neurobiological explanation complex problems that are in reality product of heterogeneous "intersecting variables that take place along the multistranded life course of each individual." In light of this, Mason recommends neuroscience to embrace a view of diversity mediated by an alternative, morally neutral, conception of degeneracy whereby variability is a condition of complex systems rather than a sign they are breaking apart (see also ▶ Chap. 111, "Neuroethics of Neurodiversity").

Future Directions

The contributions in this section draw from the vast and well established but ever developing body of anthropological understandings on ethics and consider a variety of problems in this area from a neuroanthropological perspective, unsettling long-held assumptions, providing novel ways of approaching old questions, and identifying new problems. These contributions show the potential depth and breadth of a neuroanthropology of ethics, as well as its distinctiveness. Future neuroanthropological work into ethics may also include, for example, studies investigating the implications of plural rationalities for brain function and ethical reasoning. Significant neuroethical questions in this context would include whether different forms of rationality [e.g., the elementary forms embedded in Douglas's (1978) and Thompson and colleagues' (1990) theory of socio-cultural variation or Fiske's (1991) relational models theory] are rooted in segregated neural mechanisms; under which circumstances are these mechanisms recruited; how do they constrain or bias moral reasoning; and to what extent they compete in guiding ethical reasoning and moral conduct.

An important area of development in the neuroanthropology of ethics involves the embedding of neuroscientific research in ethnographic fieldwork (Domínguez et al. 2010; Domínguez 2012; Immordino-Yang 2013). Neuroethnography, as this amalgamation of ethnography and neuroscience has been called (Domínguez et al. 2010), aims to provide an in-depth understanding of domains of cultural activity to better derive constructs, variables, and hypotheses that can be tested in the neuroscience laboratory; increase the ecological validity of neuroscience research; and shed light onto people's subjective experience including emotions, sense of self, sense of justice, preferences, and reasoning, which may be correlated with variations in brain activity and structure (cf. Immordino-Yang 2013). Neuroethnography can be a powerful tool in addressing neuroethical problems within the scope of the new anthropology of ethics, recentered as it is in the relational individual. These problems include those quoted at the outset such as how are ethical subjectivities formed, or how are they expressed in ordinary social encounters.

One domain of enquiry arousing an increasing amount of interest to which a neuroanthropology of ethics will be of relevance relates to research in neurorobotics, brain simulation, and neuromorphic computing aiming at artificially reproducing mental and behavioral properties of animals and humans. Research specifically aimed at developing robots with human (or human-like) attributes, simulating the human brain, and building autonomous devices with human-like learning and behavioral capabilities (cf. Glaskin 2012) will require a neuroanthropological understanding of what is to be human. The reason for this is that the human brain is a cultural brain and artificially reproducing mental and behavioral capabilities, which can be called truly human, will require an understanding of the human brain's mechanisms for acquiring culture and how these mechanisms interact with specific cultural milieus. Key among these capabilities will be those that allow robots, simulations, and devices to operate consistently with ethical codes of conduct.

A final fertile area of future investigation for the neuroanthropology of ethics concerns distributed cognition (see also ▶ Chap. 26, "Extended Mind and Identity"). Originally formulated by cognitive anthropologists, distributed cognition holds that "a society, as a group, might have some cognitive properties differing from those of the individual members of the group" (Hutchins 1991). From this perspective, cooperative activities, in which we may include ethical reasoning and decision making, require that a group of people form (to some extent) shared, coherent, and equivalent interpretations (Hutchins 1991). As argued earlier, the neural bases of moral agency are to be found beyond the confines of a single brain. Distributed cognition therefore offers a way of conceptualizing and investigating this central issue for a neuroanthropology of ethics. Levy (2007) has similarly remarked on the importance of distributed cognition for neuroethics as moral knowledge, he notes, is the product of the interaction of many individuals contributing different kinds and levels of expertise. Neuroanthropology can make important contributions to our understanding of the distributed character of moral knowledge, its production, and reproduction by, for example, hyperscanning during joint ethical judgment or reasoning tasks factoring in relevant cultural scripts and conventions; or by exploring the distribution of different types of neural representations pertaining to moral attitudes or conduct across a social group.

Conclusion

The papers in this section highlight the importance of neuroanthropology not only for a neuroscience of ethics (which has as object of study the neural basis of moral agency) but also for an ethics of neuroscience (which deals with the practice of neuroscience and its uses). Across both dimensions, these papers demonstrate the need for neuroethics to be sensitive to context, culture, history, and diversity as well as to the relationship between universalism and particularism, scientific fact and personal experience. Together with the areas of future research outlined above, these papers also offer new ways of approaching ethical phenomena and open up exciting new avenues of enquiry. Neuroanthropology is thus set to make a decisive contribution to our understanding of that which is the guiding light of our conduct.

Justice: A Neuroanthropological Account

Abstract

The central idea of this paper is that the directly experienced sense of justice and injustice is universal to peoples everywhere because the human brain is "wired" to experience empathy and harmony, and experience them associated with pleasure and injustice with pain. The sense of justice and injustice is shared with other big-brained social animals, particularly among social primates who share homologous neurophysiological structures with humanity. How the sense of justice plays out in societies depends upon neurocognitive, environmental,

social structural, and cultural factors that impinge upon the development of each person's perceptions, values, and personality. What a people consider as real, how they conceive of causation, and the information they credence about events will certainly vary across cultures. The sense of justice, both for the individual and among individuals in a community, is a principle ingredient in social institutions among more acephalous societies, while it may vary considerably among more complex and hierarchical societies. It is likely that all societies recognize the lack of empathy and sense of justice/injustice among abnormal individuals, and that appropriate action must be taken to protect society from actions that unsettle the balance of justice. Finally, by applying A.M. Hocart's thinking to the issue, the individual's sense of justice and injustice may become alienated from social procedures and juridical institutions, especially in highly complex, demographically diverse, and bureaucratized states.

Introduction

In the early hours of March 13, 1964, bartender and manager Catherine Susan "Kitty" Genovese left Ev's 11th Hour Sports Bar in the Queens, New York City, at the end of her shift. Kitty, an attractive, petite 28-year-old Italian-American, got into her little red Fiat and drove the approximately five miles to her apartment in Kew Gardens which she shared with her partner, Mary Ann Zielonko. As it remains today, Kew Gardens was a quiet neighborhood, verdant with trees and lawns. When she arrived, she parked her car and stepped out into legend.

As Kitty walked toward her apartment, she was attacked by a man who chased her and stabbed her in the back. "Oh my God," she screamed, "he stabbed me! Help me! Please help me! Please help me!" (Ethier 2010, p. 25). Lights went on in apartments and the attacker ran away, only to return to the scene. By then, Kitty had crawled into a building where the attacker found her, raped, and robbed her and repeatedly stabbed her. The attack lasted around 30 min. Kitty died on the way to the hospital. During the attack, at least three people witnessed the stabbings and others heard her screams and saw her lying comatose on the ground. No one did anything to intervene, and only one person called the police. Because of a New York Times article that erroneously claimed that 38 people had witnessed the crime and had done nothing to help Kitty in her distress, the story went national and was followed by an outpouring of outrage. Since then, many of the "facts" of the case have been investigated and repudiated. What seems beyond dispute is that Kitty Genovese was killed by a serial homicidal psychopath, and that numerous people were reluctant to "get involved." The case has subsequently become the textbook example of what is now known as the "bystander effect," or the "Genovese syndrome" (Manning et al. 2007).

For present purposes, the exact facts of Kitty Genovese's murder are beside the point. What is germane here is the sense of moral outrage millions of people felt when they heard of the case. In the intervening half century between Kitty's tragic murder and the present, the reader may have experienced in some form this sense of

injustice, perhaps hundreds or thousands of times. Perhaps that sense has been experienced when someone is freed from prison having been found innocent due to new exculpatory evidence, as has happened scores of times since the development of DNA profiling. Perhaps it has been experienced when there is news of politicians and Catholic priests perverting the "course of justice" to their own ends. Or may be it is felt when a killer gets less than his/her due because of the common practice of plea bargaining. Moreover, just as many times the reader has experienced the opposite, a sense of justice having been done, as when Kitty's killer was caught, tried, and sentenced, or when a friend who has gotten the promotion he/she richly deserved after long years of work, or some dispute has been resolved equitably.

In this chapter, we will explore the phenomenology of the sense of justice and parse out the universal experiential elements of the sense. It will be shown that the core of the sense of justice is universal to peoples everywhere and underlies aspects of morality that pervade the lives of most normal people in every culture, regardless of their history (see Moghaddam 2010, p. 137). This sense of justice is universal, because it is how people's brains work. In other words, there are neurophysiological structures that all humans have in common and that are triggered under certain sets of circumstances. Because we are speaking of neurophysiological structures, we may presume that they have evolved, and that we may trace the anlage of the human sense of justice in other big-brained social mammals, especially among our close relatives, the chimpanzees. We will lodge what we know about the neuropsychology of justice in a psychodynamic theory of justice, and will examine how the sense of justice plays out among non-western traditional peoples around the globe. As we shall see, the closest most human languages and cultures come to our notions of "good" and "evil" gloss something like "harmony" and "disharmony," "wholeness," and "fragmentation," "constructive" and "destructive." The sense of justice is triggered in the presence of good and evil, and is produced by a complex entrainment of neurophysiological structures mediating pleasure linked to those mediating empathy, the aesthetic and archetypal sense of wholeness, and the judgment of fairness.

The Sense of Justice

The definitions of justice of the sort one encounter among western philosophers are of little use when asking either cross-cultural or evolutionary questions, for they are both ethnocentric and designed such that they only apply *in principle* to modern humans, as sociobiologists interested in the biology of morality have emphasized (Katz 2000b; Williams 1980, pp. 275–276). They are, in a word, scientific "dead ends." For instance, John Rawls (1971) argues that justice requires reason, and by reason, he means a certain range of human cognition. Moreover, he excludes emotion from a definition of justice, which, as we will see, is crucial to understanding justice as experienced by people everywhere and animals. That is why we emphasize the *sense of justice*. Robert Solomon, in his book

A Passion for Justice, notes that: "Justice presumes a personal concern for others. *It is first of all a sense*, not a rational or social construction, and I want to argue that this sense is, in an important sense, natural" (1995, p. 102; emphasis added). Elements of the experience of justice are universal (justice, universal aspects of), while the way different peoples *conceive* of justice and injustice will vary from local culture to local culture (McParland et al. 2011).

If we explore the etymology of the word, we see that justice has to do with things being perceived as right, exact, equitable, and fair. We are "justified" in our actions when we "get it right," we "follow the plan exactly," we "strike the right balance," we have "fair dealings" with one another. Simple enough, one would think, until one gets into protracted and torturous philosophical discourses on the nature and logic of justice, and then one faces a quagmire of hyper-rational theories that prove nearly useless for the purpose of grounding a neuroanthropology of morality, much less an neuroanthropological account of justice. It is perhaps far better that we ground our approach on the relatively simple sense of justice had by almost everyone, regardless of cultural background.

As Nythamar de Oliveira (2008, p. 124) notes, "For justice nowadays, more than ever, must be rethought in sustainable, phenomenological terms, as both its social, political and environmental, cosmological dimensions must correct the shortcomings of human, all-too-human *desiderata*." From this perspective, *injustice* seems to label the sense (perception, intuition, feeling, etc.) that something is not quite right, is distinctly wrong, off-kilter, unfair, inexact, unappealing, unbalanced, or injurious. (One thinks of the iconic image of Lady Justice carrying a balance scale and blindfolded against bias and special interests – sometimes a sword as well – an image that dates to the Roman goddess *Justitia*.) This sense is rarely if ever fully articulated or dispassionate. The sense of justice is inevitably accompanied by positive affect, injustice by negative affect. Thus, *the core of the sense of justice (justice, definition) is the empathetic pairing of positive feelings like pleasure, satisfaction, contentment, joy*, etc. *with the perception or intuition that someone's unfair/undeserved situation has been put to right, has been balanced, is now fair, and perhaps even healed* (same root as "whole" and "holy").

Justice and the Brain

The sense of justice is universal across cultures, and thus is an experience that must be mediated by inherent mechanisms in the brain (Laughlin 2011; Laughlin et al. 1990). This is yet another phenomenon amenable to a cultural phenomenological approach (see Csordas 1990, 1994; Throop 2009). However, for the purposes of explanation, we may use a relatively new strategy for accounting for such phenomena that has been developed in anthropology under the designation *cultural neurophenomenology* – a perspective that links the neurophysiology of direct experience with cultural factors (see Laughlin and Throop 2006, 2008, 2009). We humans are social primates, and our brains, like those of our primate relatives (see Russon 1996), are "wired" for social interactions and social learning by way of

mimicry. In other words, we are a "mimetic" animal – we are "wired" to learn by imitating our elders and peers (Garrels 2011). In their classic study, Meltzoff and Moore showed that newborns as early as 18-h old can reproduce tongue, mouth, facial, and other movements displayed by the adult they are observing (see Meltzoff and Moore 1977, 1983a, b, 1997; Meltzoff 1985, 2002). This proclivity for social mimicry is conditioned during our early development by both inherent neurogenesis and the style of nurture, actions, language(s), values, world view, and other cultural attributes of our parents and other caretakers. We are products of both our inherent neurophysiological mimetic nature and our culturally conditioned upbringing (Garrels 2011). The development of a person's sense of justice occurs in the context of this dialogue between neurocognitive mimetic growth and social conditioning. And as we have seen, the experience usually consists of a complex of elements, each one presumably mediated by discrete neurophysiological mechanisms.

Empathy

There is now a tremendous scientific interest in the capacity for and experience of empathy (or, sympathy; Wilson 1993), especially in anthropology (Hollan and Throop 2011; Throop 2008a, b, 2010a, b), primate ethology (De Waal 2009), forensic psychiatry (Baron-Cohen 2011), psychology (Haidt 2012; Farrow and Woodruff 2007), and neuroscience (Decety and Ickes 2009; Keysers 2011; Gallese 2003, 2005a, b). Of course, interest in the phenomenology of empathy dates back much further – at least to Edith Stein's 1917 classic *Zum Problem der Einfűhlung* (*On the Problem of Empathy*), a doctoral dissertation she completed under Edmund Husserl in 1916. This recent renewed interest arose on the tail of the discovery during the 1990s of mirror neurons by Giacomo Rizzolatti and his associates that appeared to lay the groundwork for a science of empathy (Braten 2007; Lepage and Théoret 2007; Iacoboni et al. 1999; Rizzolatti et al. 1996; Gellese et al. 1996).

The discovery of neural networks that are inherently "wired" to understand and mimic the actions of others cannot be overemphasized in the study of justice by either anthropologists studying morality or neuroethicists – especially those studies that have focused upon *mirror neurons* (Gallese 2005a; Gallese et al. 2007; Rochat et al. 2008, p. 231). It is apparently these systems that provide the structural foundation for empathy. By way of empathetic processing, a person may mimic the other's actions either directly or by imagining those actions and effects, and vicariously feel the other's joy, satisfaction, fear, pain, suffering, etc.

Empathy not only refers to action understanding and judgments pertaining to fairness; it also involves affect (Greene et al. 2001; Gallese et al. 2004). Wicker et al. (2003) have shown, using functional neuroimaging, that while mirror neurons mediate action understanding, they also mediate empathetic feelings. They tracked the activity of brain centers mediating the feeling of disgust in subjects that were stimulated with malodorous smells. Their facial gestures were

videoed and shown to other subjects in the absence of the smells. The same area (the so-called core disgust system: the anterior ventral insula which is located in the limbic system deep within the lateral sulcus) becomes active while viewing facial gestures signaling disgust as happens if one perceives a disgusting smell. Interestingly, direct electrical stimulation of the area will produce noxious sensations in the mouth. In addition, Amit and Greene (2012) have shown experimentally that if the sense of justice involves imagery, the affective influence upon moral judgments will likely be greater.

Fairness and Pleasure

As we have seen, the sense of justice is accompanied by positive affect and injustice by negative affect. In a series of experiments, Singer et al. (2006) have shown, using neuroimaging techniques, that perception of fairness is coupled with enhanced empathy and feelings of pleasure, while perception of unfairness is correlated with a decrease in empathy and pleasure. The areas involved in mediating the pleasure sense, or lack of it, include the nucleus accumbens (a structure that plays a central role in reward) and the orbito-frontal cortex (which mediates both decision-making and emotion/reward). The pleasure aspect of the sense of justice leads quite naturally to the interesting question of the aesthetics of justice (Ben-Dor 2011; Resnik and Curtis 2011). For instance, it is quite common for the sense of justice to be expressed in artistic forms cross-culturally (e.g., see Soroush 2007 on justice and beauty in Islam).

Empathy also involves feeling the suffering of others (Jackson et al. 2005; Botvinick et al. 2005). Focusing on the apperception of pain in others, Singer et al. (2004) have shown, using brain imaging, that a portion of the pain system is activated in the empathizing observer. The areas of the brain that light up when either feeling pain oneself, or observing pain in a loved one, are areas in the anterior insula, rostral anterior cingulate cortex, areas in the brain stem, and cerebellum.

Higher Centers of Empathy

Empathy, of course, involves more than affect and social identification with the pleasure and suffering of others (Katz 2000a). It also involves those areas of the brain that mediate social involvement, and especially those areas of cortex, like the prefrontal lobes, that modulate feelings and control attention and judgment. Seitz et al. (2006, p. 743), using surgical lesion data, have shown that: “These data complement the consistent observation that lesions of the medial prefrontal cortex interfere with a patient’s perception of own bodily state, emotional judgments, and spontaneous behavior. The results of the current meta-analysis suggest the medial prefrontal cortex mediates human empathy by virtue of a number of distinctive processing nodes.” Shamay-Tsoory et al. (2003), using a comparative lesion approach, have also isolated areas of the prefrontal

cortex – especially the right ventromedial prefrontal cortex – in the mediation of empathy. Among other things, the prefrontal cortex mediates our perception of the intentions of others, and is fundamental to social communication and interaction (Changeux 2002, Chap. 4).

Putting all of this together, the experience of empathy clearly has both an affective and cognitive aspect, both of which are critical to the sense of justice. Indeed, it is the presence of this deep-seated and inherent capacity for empathy that likely makes the difference between morality and mere cultural convention – a distinction that appears to also be universal (Blair and Blair 2011). Simon Baron-Cohen (2011, pp. 27–41) has similarly integrated many of these cortical and subcortical areas into what he calls the "empathy complex." His approach, however, includes more cognitive functions involving empathy than has been included in the present definition of the sense of justice, for his approach would by definition be limited to humans, rather than revealing the more universal and evolutionary elements of justice. What makes his approach especially interesting to us is that he shows how, by whatever psychological instrument used, the presence and intensity of empathy in any natural population of humans distributes along a bell curve, with most people falling in the mid-range and a few manifesting little or no empathy and a few manifesting intense affect (2011, pp. 20–27). It would be interesting to know if this kind of normal distribution occurs among other social animals. Moreover, it is becoming clear that the sense of justice, present in the child, undergoes a process of development in interaction between the child and his/her social environment (see Killen and de Waal 2000). The kinds of problem solving and judgments associated with the sense of justice range in complexity across individuals in any culture from the very concrete to the highly abstract (Rest et al. 1999).

"Wild" Justice

Among social animals, it makes sense to define justice in terms that fit with their situation: "Justice is a set of expectations about what one deserves and how one ought to be treated" (Bekoff and Pierce 2009, p. 113). In other words, animals have an inherent sense of fairness and normalcy, and react emotionally and even violently when these expectations are trampled on. Anyone with a pet dog will know how their beloved companion reacts when treated unfairly. So it is with human beings. Because the sense of justice is inherent in the structure of the human nervous system (see Wilson 1993), it must have evolved as part of a complex of neurophysiological features that mediate the psychological dimensions of sociality and sociability in our species, as well as other extinct species of hominins going back millions of years. Naturally, we have no direct phenomenological evidence of the sense of justice in any hominin species other than our own. *Homo habilis* and *Homo erectus* are long dead, and living chimpanzees and bonobos, like the family dog, have no language sufficiently complex to chat with us about their moral experiences. Yet it is reasonable to suppose that the anlage of our sense of justice

among earlier hominins were fairly similar to our own, perhaps without the level of self-reflection and cognitive complexity we associate with full-blown cultural theories of justice.

Inferring from their patterns of behavior and social interactions (dominance interactions, play, food-sharing, altruism, etc.), it is apparent that large brained social animals (justice, among social animals) do experience a sense of justice, as well as a spirit of cooperation and sharing (Bekoff 2007, Chap. 4; Bekoff and Pierce 2009; de Waal 2006, 2009; de Waal and Lanting 1997, p. 41; Lorenz 1964). Indeed, Marc Bekoff and Jessica Pierce make no bones about it. In their book, *Wild Justice* (2009, p. 1), they state: "Let's get right to the point... we argue that animals feel empathy for each other, treat one another fairly, cooperate towards common goals, and help each other out of trouble. We argue, in short, that animals have morality." With respect to justice, they go on to reason: "The principle of parsimony suggests the following hypothesis: a sense of justice is a continuous and evolved trait. And, as such, it has roots or correlates in closely related species or in species with similar patterns of social organization. It is likely, of course, that a sense of justice is going to be species-specific and may vary depending on the unique and defining social characteristics of a given group of animals; evolutionary continuity does not equate to sameness" (2009, p. 115).

We could present relevant data for a wide range of animal species, including elephants, dolphins, canids (including the domesticated dog) and various birds (see Bekoff and Pierce 2009; Peterson 2011; Hauser 2000 for broad discussions of morality among social animals), but our space is limited and it makes sense that we should stick to our primate relatives, especially the chimps and bonobos. Technically speaking, our closest living primate relative, determined by DNA data, is *Pan paniscus*, the bonobo (once called the "pygmy chimpanzee;" see de Waal and Lanting 1997; Lonsdorf et al. 2010; Wrangham et al. 1994). But *Pan troglodytes*, the "common" chimpanzee, is also close genetically and hence relevant. Also, much of the data suggest that the origins of human morality are to be found in processes widely distributed among social primates (Flack and de Waal 2000).

Sense of Justice in Chimps, Bonobos, and Other Primates

We are unable to directly "get into the mind" of another animal. Rather, we have to infer their experiences from available behavioral and neurophysiological data (see Russon et al. 1996; Cohen 2010; Aureli and de Waal 2000). Fieldwork among free-ranging primates and laboratory experiments suggest that empathy and the sense of justice is to be found during the activities and decision-making of primates involved in sharing (especially of food and grooming), the resolution of potential conflict, and in perception of and reaction to conditions leading to the experience of sympathy (or empathy).

The capacity for empathy can also manifest in the marked ability of chimpanzees to deceive others (Byrne and Whiten 1990). De Waal and Aureli (1996, p. 102)

offer an example of this phenomenon when Yeroen, a male chimpanzee living in the Arnhem Zoo Chimpanzee Colony in the Netherlands, was wounded by a rival male: “The wound was not deep and he walked normally when out of sight of his rival. However, for a week, Yeroen limped heavily each time he passed in front of his rival. If injuries inhibit further aggression, Yureon’s attempt to create a false image of pain and suffering may have served to delay renewed hostilities.” This kind of deception presumes that Yureon is capable of anticipating the feelings, perceptions, and judgments of the other. Chimpanzees and other primates, as well as other social mammals, stick up for their kin and friends during episodes of aggression and conflict, and chimps are famous for kissing and embracing each other after fights, a ritual enactment of empathy that would appear to calm ruffled feelings and reestablish peace (de Waal 2006, p. 19). Bonobos appear to be especially sensitive to others’ experiences, to what they may be feeling or intending, and what they need to do to keep relations peaceful and address their fellows’ suffering (de Waal and Lanting 1997, p. 154).

Justice in Cross-Cultural Perspective

It is perhaps redundant to emphasize that moral animals are social animals. It is doubtful that solitary species like the red fox experience a sense of justice, empathy, or any other moral affect/cognition neural entrainment for that matter. Hence, the manifestation of moral experience among humans usually plays out in a social context (McParland et al. 2011). Although the sense of justice, as we have seen above, is rooted in universal neural mechanisms, living in a family and community has an impact on how that sense manifests in different social environments. At the same time, there always exists a tension between the experience of individual persons and the social context, regardless of the society involved (O’Manique 2003, p. 133). The inevitable social context of the sense of justice and moral judgments generally is far more evident among non-technocratic, traditional societies than is the case in our own materialistic postindustrial society. This is why the study of morality and culture has occupied anthropologists for generations (see d’Andrade 1995; Throop 2009).

Justice in Polyphasic Cultures

One of the reasons for this disparity is how we in the west interpret experiences had in *alternative states of consciousness* (ASC) – experiences had while dreaming, pursuing vision quests, meditating, carrying out religious rituals, during drug trips, etc. In western technocratic societies, we are taught to ignore and even abjure experiences of this sort. We live in a *monophasic* (people ignore experiences had in other than “normal” waking consciousness) social environment (Laughlin 2011, pp. 62–66; Laughlin et al. 1990, pp. 154–156, 289–291; Laughlin and Throop 2001; Lumpkin 2001). The avoidance of socially meaningful interpretations of ASC is part and parcel of the conditioning necessary for the

extreme egoistic self-identity relished in the west, and incidentally for the pervasive sense of alienation in our society today.

Most non-western, non-materialistic human societies on the planet are *polyphasic* societies. Polyphasic cultures are markedly different from the ones to which most of us belong. These are societies in which experiences had in ASC are conceived by people as different domains of reality, not as unreality. Indeed, most people on the planet, even those in monophasic cultures, rarely if ever make a distinction between experienced reality and extramental reality in their everyday lives. Their sense of identity incorporates memories of experiences had in dreams and other ASC, as well as in waking life. Non-western people may in fact have no word in their native tongue that glosses precisely "dream" in our English sense. What we call a "dream" may be considered by others to be the polyphasic ego (soul, spirit, shadow, etc.) of a person experiencing another domain of reality during sleep. Dream experiences, just as waking experiences, inform the society's general system of knowledge about the self and the world, as well as the development of a person's identity. One can thus understand why ethnographer Jean-Guy Goulet's hosts among the Guajiro (a South American people) would not allow him to live with them unless he "knew how to dream" (1994, p. 22).

Why does the distinction between monophasic and polyphasic cultures matter vis-à-vis our discussion of justice (justice, in polyphasic cultures)? Because how a person interprets and acts upon the sense of justice (or injustice) depends in part upon how entangled one feels and knows himself/herself to be in the commonweal. Here in the mostly urban west, we can live in an apartment for years and not know many, if any of our neighbors. In traditional societies, everybody typically knows everybody else, has grown up with many of them, and moreover directly experiences the ineluctable interconnectedness between themselves and both the community and the physical environment. The experience of entanglement is heightened during dreams and other ASC where reality comes to be known as both physical (what one experiences in what we call waking consciousness) and spiritual (what one experiences in ASC when the normally invisible connections between things and events become manifest).

In traditional societies, such experiences lead to and confirm mythological accounts of the world. Mythological worldviews usually take the form of a cosmology in which everything is interconnected in space and time (Laughlin and Throop 2001). In such a cultural context, the view of every man "is an island" can hardly arise. Extreme egoism of the sort we encounter in modern technocratic societies is rare. Everybody's well-being is dependent upon everybody else's, as well as the well-being of spiritual beings and the cosmos in general. The relevance of this factor in traditional cultures will become clear in a moment.

Justice and Psychosocial Abnormalities

Considering that the sense of justice is universal to people with a normal brain, and that the empathetic aspect of that sense distributes along a normal curve

(see above), it is interesting to look at what this means to research into neuropsychological abnormalities in which little or no sense of justice or empathy is experienced. We know, for instance, that extreme autism is associated with what Vittorio Gallese (2006, p. 7) calls a lack of "intentional attunement" with others – an inability to internally construct a socially shared world full of others with whom one feels empathy. Gallese points at the likely disruption of mirror neuron networks during development among autistic individuals. Although otherwise quite dissimilar from autism, the same is likely true for psychopathy (Blair et al. 2005). Psychopathic individuals develop serious social and moral deficits, often due to early damage to their prefrontal cortex (Anderson et al. 1999; Saver and Damasio 1991), the area of the brain primarily responsible for socio-moral judgments and executive mediation of social affect. This leads to a profound empathetic dysfunction (Blair 2007) among individuals who may or may not perpetrate violent behaviors. Because of this dysfunction and associated low affect, psychopathic individuals very likely have little or no sense of justice – zoologically speaking, being more like the solitary red fox than the highly social arctic wolf. There is some evidence from state-level societies to suggest that psychopathy occurs across cultures (Cooke 1995, 1998; Shariat et al. 2010), but there have been distressingly few cross-cultural studies of psychopathy carried out among traditional peoples (Pitchford 2001).

However, it follows from the perspective developed here that one would expect to find virtually all societies recognize the lack of empathy or sense of justice in some of its members, and to conceive of, to speak about, and to act in respect to such individuals as abnormal (see also Moll et al. 2005). For instance, anthropologist Jane Murphy (1976) compared the Yoruba people of Nigeria with the Inuit people of Alaska with regard to how they conceive and respond to psychopathy-like behaviors and personality characteristics. Both societies recognize something akin to psychopathy, and consider the condition to be dangerous and abnormal. The Inuit label such individuals *kunlangeta*: "This is an abstract term for breaking of the many rules when awareness of the rules is not in question. It might be applied to a man who, for example, repeatedly lies and cheats and steals and does not go hunting and, when the other men are out of the village, takes sexual advantage of many women – someone who does not pay attention to reprimands and who is always being brought to the elders for punishment" (Murphy 1976, p. 1026). The typical reaction to such individuals was for the elders to kill him, for they considered the condition un-treatable.

Justice, Culture and the Law

It is thus not surprising that the sense of justice plays out in most traditional societies in social rituals – especially as ritual forms of adjudication that we westerners interpret as "courts" or "councils." (That is why most of the discussion of justice in anthropology centers around "law" and judicial institutions, and why the anthropology of law is a major ethnological subdiscipline

(see Miller 2001; Niezen 2010; Rosen 1989; Moore 2005; Donovan and Anderson 2003)). When the author was doing ethnographic fieldwork among the So – a pastoral and horticultural people living on three mountains in Northeastern Uganda – he transcribed a number of what we might call *moots* (Bohannan 1989, pp. 160–161) – a conflict brought before the council of elders (all male, the So being a patrilineal and patriarchal society). The social dimensions of the felt sense of justice and injustice represented in many of these moots are quite indicative of the kinds of juridical institutions for conflict resolution found among tribal peoples generally, and illustrate the extent to which the emotional factor in the sense of justice and injustice becomes clear. Moreover, the relationship between the sense of justice and social process is very likely similar to the prevailing situation going back tens of thousands of years, well back into the Upper Paleolithic.

To give a flavor of the kind of situation we anthropologists encounter in the field, the author will share this transcript taken from our ethnography of the So – a moot we will call the "Case of the Purloined Cow" (Laughlin and Allgeier 1979, pp. 128–131):

> A young man has come before the council accusing an old man (L and N, respectively) of having taken and killed one of his cows without permission. Just what N used the cow for is not clear. L made his accusation before one of the elders of the tribe who in turn called a meeting of all the elders the following morning. Approximately 75 elders were in attendance for the meeting. When all were gathered, L stood before the elders and made his accusation and also stated that N had repeatedly refused to repay the cow to him and that it had been over two years since the incident. L then sat down.
>
> Elder: Supports L's accusation (he and others apparently aware of the situation) and stated that in his opinion it was bad (*erono*) to kill the cow of another without the owner's permission.
>
> Elder: Addressing N, "Did you obtain L's permission before taking his cow?" (N replies in the negative.) "Then you must have your cow ready when the owner comes for repayment."
>
> N: "Why complain? I will payu the cow."
>
> Elder: "Keep quiet! I will speak. The man [L] is accusing you of killing his cow without permission. The question is whether you will pay him a cow in return. It is wrong (*erono*) that you did not ask."
>
> Elder: You [N] are guilty. When the owner of a cow you have taken asks for a cow in return, you should pay it."
>
> At this point an old woman (the mother of L sitting outside the circle of elders) interrupts to ask that the matter be taken directly to the police [i.e., the district office of the Uganda police]. She does not wish the elders to reach a decision here. She interrupts a number of times throughout the proceedings while remaining seated outside the council grounds (*omut*).
>
> Elder: "You two must talk kindly to each other and settle the giving of the cow. You must again ask N for a cow and if he again refuses you must accuse him again before us."
>
> L: "It is not bad to kill a cow of another if he knows it will be returned, but I have no assurance with this man." [L is visibly angry.]
>
> Elder: "Do not quarrel! You are killing this man from quarreling too much. Ask slowly for your cow."
>
> There is general outburst from various participants including L's mother. Some of the elders pound the ground with their walking sticks for order.

Elder: "You [N] should pay the cow today. It is not good for this matter to be taken to the government."

L's mother demands the matter be taken to the police.

Elder: "Do not say that! You will spoil the matter."

L's mother: "Take it to the police! We must have the cow quickly."

L: "I want my cow today!"

Elder: "You [N] must go today and select a cow for L. Do you [L] want a cow or a bull?" L indicates that he only wants a cow. "Will you [N] give this man a cow in the next while?"

N: "I am going to search somewhere for a cow."

A feeling is expressed on the part of some of the elders that the meeting should be postponed both because of the absence of the government-appointed chief (*Mukungu*) and because it will give N a chance to obtain a cow.

Elder: "Why are you saying postpone the meeting if the cow is not to be given today?"

Elder: "You [N] must tell in front of all the people here that you will pay the cow so all will know."

N remains silent.

Elder: "If we take this matter to the government, it will get bad, serious. We must settle this ourselves."

At this point several elders suggest that five days be given N to supply the cow. If it is not returned by that time, then all he elders will meet again.

L: "It is alright with me, but ask N."

N: "It is very difficult for me to find a cow unless I go to ask friends [meaning lineage relations] for one. Is it alright with you [L] if I go in search of this cow? I will consider this a serious matter."

L agrees.

Elder: "You can search for five days. Do not take this matter to the police. All of you [L and his party] go and wait for five days. If at the end of that time the cow is not replaced, we will gather again."

The replacement cow was indeed found among N's relatives and given back to L, thus bringing the matter to a close without appeal to external (and generally despised) government authority. Had the matter been taken to the police, the elders would have lost control, N would have been called a "thief" in English jurisprudence and likely jailed, and the collective sense that justice had been perceived to be done would have failed. From the So point of view, it was really a matter of balance or reciprocity of exchange between two groups of people, L's lineage (the lineage collectively, not the individual, own cattle) and N's lineage. There was another aspect that was enacted repeatedly in these proceedings – an intolerance of extreme negative emotion. When an elder intervenes in a quarrel and says "you are killing this man with your words, or accusations," *they mean it literally*. African cultures generally hold that to say something is tantamount to doing it. Thus, to get angry and threaten someone is taken very seriously. Every effort is made by the elders to "keep the lid on," to cool the emotions of disputants and avoid potential violence between individuals and feuds among lineages – eruptions that can easy lead to social disharmony.

As we mentioned above, the So are like most traditional peoples on the planet in that their sense of justice has a lot to do with perceived balance in matters of reciprocity. There is an understanding among such people that there is a natural balance with respect to both physical processes and social transactions. The sense of injustice among people is triggered when this balance is perceived to have been disrupted.

Reciprocity, Natural Balance, Healing, and Justice

The Navajo (Navajo Indians) are a group of horticulturalists (in some areas intensive agriculturalists) and sheep herders who inhabit the largest reservation in North America. Central to the Navajo world view and moral philosophy is the concept of *hozho* (or *hǿzhǿ*; see Witherspoon 1977; McNeley 1981; Farella 1984). The connotations of *hozho* are too broad to be precisely glossed in a single English word, but are usually translated as meaning "beauty," "peace," or "harmony." Perception of the loss of *hozho* in some circumstances is similar to, if not synonymous with, the sense of injustice (see Yazzie 1994, 1995). The emphasis in traditional Navajo culture is always toward reestablishing harmony (*hozho*), both within the individual and between individuals within the community. The Navajo term for holding a "justice ceremony" today is *Hozhooji Naat'aanii* (Bluehouse and Zion 1993) – borrowed from the ancient Chief Blessingway ceremony, a healing ceremony for reestablishing *hozho*.

As with all Native American societies, the Navajo have been impacted by Anglo values and institutions, and for a long time, their "criminal" matters were handled by western-style courts. Recent years have seen a return to traditional approaches to jurisprudence, and to the emphasis upon regaining harmony, peace, and healing (see Nielsen and Zion). Currently, most of the talk about "peace-making" and "restorative justice" (Sullivan and Tifft 2005; Nielsen and Zion 2005) emphasizes equality, reciprocity, and restoration of social harmony. In doing so, they conceive of the traditional approach to seeking justice to be diametrically opposite to that of the dominant Anglo "adversarial" systems. From the Navajo point of view, Anglo court proceedings often do not result in addressing the lived experience of injustice felt not only by the litigants, but also their families and the community at large. What is lost in Anglo proceedings is the recognition of the rippling waves of impact upon others. This recognition has more recently been acknowledged in Anglo jurisprudence with the introduction of victim impact statements at the end of the trial. But Navajo culture and peace courts fully acknowledge the interconnectedness of people with families and community as a whole, and the process keeps in mind as much as possible the sense of injustice felt by many who have been affected. In a word, the intent of the peace court process is the restoration of the sense of justice throughout the community.

In many ways, the way restorative justice plays out among the Navajo is representative of other Native American and Canadian First Nations peoples. The reification ("rediscovery") of traditional culture seems to happen with a good deal of editing (Povinelli 1993, p. 126). Along with emphasis upon restorative justice come problems in implementing systems forged in bygone, pre-conquest days into a more modern and socially complex situation. The Coast Salish people of British Columbia are a case in point, for in their distant past both peaceful and violent responses to disharmony routinely occurred, and not everyone was treated equally (Miller 2001, pp. 5–6). Moreover, the modern emphasis upon equality of social status belies the complex stratified political society characteristic of pre-Columbian days (Miller 2001, pp. 5–6).

A.M. Hocart and the Evolution of Justice

Political and cultural editing issues aside, it is beyond argument that individual societies range in the extent to which their institutions address peoples' sense of justice and injustice. Indeed, societies range on a continuum from those whose institutions prioritize their peoples' sense of justice to societies that do so minimally, if at all. In the latter case, this does not mean that people no longer manifest a sense of justice, but rather it is to whatever extent it is ignored in judicial proceedings. The demographically larger and more hierarchical and complex the justice system, the less likely are the institutions going to prioritize in favor of addressing that sense. Meanwhile, this sense, being universal to all peoples, remains present and is an ingredient in the efficacy of all local community systems. Some emphasis upon the therapeutic process seems to characterize most such systems.

In order to model the relationship between the inherent sense of justice/injustice and justice-oriented social institutions, it is useful to appeal to Hocart's theory of the evolution (justice, evolution of) of society. Arthur Maurice Hocart (Hocart, Arthur Maurice) (1883–1939) was a British sociocultural anthropologist living and working during the early decades of the twentieth century (1970[1936]). Hocart argued that all humans on the planet have at least one thing in common – *the quest for life*.

> Keeping alive is man's greatest preoccupation, the ultimate spring of all his actions. To keep alive he must have food. But man is not content merely to seize it and devour it. He looks ahead to ensure future supplies. Besides storage he also devised a technique for making food abound, a technique consisting of charms, spells, magic, and so on. (Hocart 1933, p. 133)

At some point in the ancient past, our ancestors became sufficiently self-reflexive to not only live, but *to conceive of life*. The quest for life among humans is a broader and more culturally nuanced occupation than merely assuring enough food and the procreation of the species – it involves the maintenance of vitality, longevity, equitable resource distribution, alliance among groups, comprehension and adaptation to the fact of death, and peaceful and harmonious social relations. The quest is essentially a social occupation in the sense both of cultural conditioning about what constitutes the good life, and the collective actions taken to assure the good life.

Hocart, being an anthropologist, realized that many peoples on the planet are not governed (Hocart 1970[1936], p. 128). And yet ungoverned peoples also seek the good life, value peace and harmony, and experience a sense of justice and injustice that must be addressed in a social context. The quest for life and for justice predates governance by untold thousands of years. How does this play out? For Hocart, the inherent need for life, for justice, leads to social solutions that, if they work satisfactorily, become institutionalized – hence the widespread institution of the moot we have described it above.

The Good, the Bad, and the Ugly: Justice and the Bureaucratic State

The genius of Hocart is obvious from his straightforward and simple insistence that the role of consciousness in human affairs is the biological, social, and cultural quest for the good life, and part and parcel of the good life is justice (Hocart 1934, 1970[1936], Chap. 10). People living in simple acephalous societies ("acephalous" means without a leader, but in Hocart's sense, the term implies an egalitarian society without a hierarchical system of governance) are no different than people living in complex hierarchical societies in that they all want the same fundamental thing – life. The furtherance of that universal desire may lead different peoples in different directions depending upon how they construct a technical and social adaptation to local contingencies. But underlying it all is a common, inexorable process of development. In the pursuit of the good life, the organization of the acephalous band and tribal society gradually develops a hierarchy – it loses that simpler horizontal organization typical of kin-based band, clan, moiety, and segmentary lineage systems and takes on the form of hierarchical officialdom. "Gradually the high rise higher, the low sink lower, until the state is rearranged in a vertical hierarchy such as ours" (Hocart 1970[1936]), p. 292). Within this pressure for hierarchy and coordination arises the process of *specialization of role*. People are taken into the government and taught to do jobs that no longer are carried out within and for the old kin-based system. Instead of disputes being settled by the elders with whom one lives, as in the So case above, the society develops specialized roles for jurists – individuals who develop a specialized knowledge of the law and procedure, but whom parties to the dispute may well not know.

Moreover, specialization becomes more and more constraining upon the individual's own quest for life. People in our modern technocratic society are forced to adapt to roles that no longer fulfill that primal desire – the quest for the good life. Much of the pressure is unavoidable, for it is driven by demographics – as the population grows, the competition for the means of attaining the good life, including justice, becomes more and more exclusionary and stressful. Somewhere along the line, the "coordinating system" (the bureaucratic state with its "criminal justice system," its system of codified laws and regulations, its amoral corporations, etc.) absorbs more and more of the resources available to the society – it becomes as it were a society within the society – and increasingly feeds its own needs, rather than the needs that gave rise historically to the institution in the first place. The coordinating system ceases to address the needs that initially gave rise to the system, but because it is now institutionalized – and worse, *bureaucratized* – it thwarts the existence of alternative institutions that might answer that primal need more directly and effectively. In the end, society becomes so fragmented and specialized that the result is the increasing alienation of the people who find their natural, innate quest for life – and justice (justice, alienation from the sense of) – thwarted and frustrated.

This alienation is nowhere more evident than in addressing the sense of justice/injustice, and the pursuit of social justice. The "peace court" restorative justice

movement among many aboriginal peoples is a tacit recognition of the experienced disjunction between the direct, individual and group quest for justice, and bureaucratically administered social processes.

Conclusion

Summarizing, the directly experienced sense of justice and injustice is universal to peoples everywhere. It is universal because the normal human brain is “wired” to experience empathy and harmony, and experience them associated with pleasure (and injustice with pain). We have seen that the sense of justice and injustice is shared with other big-brained social animals, particularly among social primates who share homologous neurophysiological structures with humanity. Just how the sense of justice plays out in societies depends upon neurocognitive, environmental, social structural, and cultural factors that impinge upon the development of each person’s perceptions, values, and personality. What a people consider to be real, how they conceive of causation, and the information they credence about events will certainly vary across cultures, especially when monophasic and polyphasic societies are compared. The sense of justice, both for the individual and among individuals in community, is a principal ingredient in social institutions among more acephalous societies, while it may vary considerably among more complex and hierarchical societies. It has been suggested that it is very likely that all societies recognize the lack of empathy and sense of justice/injustice among individuals with neuropsychological disorders, and that appropriate action must be taken to protect society from potential harm. Finally, by applying A.M. Hocart’s thinking to the issue, how the individual’s sense of justice and injustice may become alienated from social procedures and juridical institutions has been demonstrated, especially in highly complex, demographically diverse, and bureaucratized states.

People still experience a sense of justice and injustice while living in complex bureaucratic states, but whether that sense remains important, or is addressed directly by social justice institutions varies enormously across nation states and global, transnational juridical institutions (e.g., the Hague). Recognition of the failure to address the individual sense of justice has in recent decades led to the introduction of “victim impact statements” during the sentencing phase of major crimes in many countries and jurisdictions (see e.g., Erez and Tontodonato 1992; Bandes 1996). While this development has undoubted therapeutic effects for victims and their sense of justice, it is unclear whether such statements have any actual effect upon the judicial process (see Davis and Smith 1994; Erez et al. 2011).

When Kitty Genovese met her end on that early morning in 1964, it set the stage for a reflection upon the sense of justice and injustice felt by millions of people who had never met Kitty, as well upon the failure of social responsibility and the role of the modern justice system in addressing the sense of injustice felt by those who knew and cared for the victim. Nearly a half century has passed since these events,

and yet the issues of justice continue to reverberate through society. Kitty's killer is a psychopath, self-confessed serial rapist and murderer who remains in prison, despite numerous applications for parole. He is again qualified for a parole hearing in November 2013, and as always, Kitty's brother Vincent and other members of Kitty's family, as well as others impacted by the terrible crime, will be in the parole board room to see that he once again is denied parole and remains incarcerated. This speaks volumes about the reality and depth of the sense of justice and injustice, and how difficult it is for modern technocratic justice systems to directly address this inherent sense.

Abstract

This chapter explores free will, agency, and the brain. It employs a critical structural realist (CSR) approach to assist investigators in the study of will and of the possibilities for freedom. The position is argued in three sections. First, there is a preliminary discussion of an influential modern concept of will that identifies one of its weaknesses. The section concludes with an introduction to CSR. The following section addresses this weakness by rethinking will in CSR terms as the operation of a cultural, reflexive human brain. The following section speculates upon the implications of such an understanding of will for freedom. At this juncture, a notion of agency is offered and its relevance to free will is discussed.

Introduction

A worthy essay should end with a bang – a eureka moment – when readers expostulate, "wow, that's it!" This chapter considers free will, agency, and the brain. It utilizes a critical structural realist (CSR) approach (Reyna 2002, 2012) to aid observers to investigate the human will and its possibilities for freedom. This position is formulated in three sections. First, there is a preliminary discussion of an influential modern conception of will, identifying one of its key weaknesses. This section concludes with an introduction to CSR. The following section addresses this weakness by rethinking will in CSR terms as the operation of a cultural, reflexive human brain. The final section speculates upon the implications of such an understanding of will for freedom. At this juncture, a notion of agency is offered, which leads to something of a eureka moment in the conclusion.

Inquiry concerning human will and the possibility of its freedom has exercised Western thought since the Greeks. Most of this speculation has been philosophic in nature. CRS is a view that reality is knowable to different degrees; that it consists overwhelmingly of structures; and that knowledge of these is needed for the formulation of normative judgment. An advantage of CRS is that it focuses attention upon something neglected in philosophical accounts of free will, the material structure of will. But in order to develop a CSR approach to free will, let us first consider a central, modern view of this construct.

Something Missing?

A Modern Problematic of Will

The philosophic problematic of will [will, functional accounts of] emerged during the Enlightenment and greatly developed over the nineteenth century. Two key Enlightenment figures of this problematic were David Hume and Immanuel Kant. By will Hume (1739–1740) meant "nothing but the internal impression we feel and are conscious of, when we knowingly give rise to any new motion of our body, or perceptions of our mind" (1739–1740, p. 399). Will for Hume is something internal to humans that "knowingly" gives "rise" to the body's motions, i.e., actions, and/or its mental perceptions, i.e., thought. Hume informs his readers what will does, and in so doing gives a functional account of it, but not what the something is performing will's functions. Nowhere does Hume explicate what will is.

Hume was the culmination of British eighteenth century empiricism. Kant, working several decades later on a project to synthesize empiricism and idealism, operated with a notion of will influenced by Hume. Kant's will [will, as practical reason] (1785 [1997]; 1788 [1956]) is practical reason. As with Hume, Kantian will is internal to humans. It operates by a reasoning that applies a general principle of action pertaining to ethical duties to one's particular situation, because "Who wills the end, wills (so far as reason has decisive influence on his action) also the means

which are indispensably necessary and in his power" (1785 [1997/1949], pp. 84–85). So for Kant, as with Hume, will "knowingly" – specifically through reason – gives rise to action. Further, Kant's understanding of will is functional like Hume's, explicating what will does. There is talk of "faculties" and "categories" in Kant's work, but the something that uses these to execute the function of practical reason is passed over in silence.

The Enlightenment was followed by a rise of Romanticism and a decentering of reason's hold over human action. Arthur Schopenhauer, who imagined himself a follower and critic of Kant (see especially Schopenhauer 2000 [1818]), was an early nineteenth century exponent of this trend. About will he affirmed,

> In my language, this means that the objective world, the world as representation, is not the only side of the world, but merely its external side, so to speak, and that the world has an entirely different side, which is its innermost being, its kernel, the thing-in-itself. This we shall consider . . . 'will'. . . (2000 [1818/1969], p. 31).

Schopenhauer's will resembles that of Hume and Kant, being something internal to humans, their "innermost being." But what is this being? Troxell, a student of the philosopher, puts it as follows:

> [Schopenhauer's] . . . will is a blind, unconscious force that is present in all of nature. Only in its highest objectifications, that is, only in animals, does this blind force become conscious of its own activity. Although the conscious purposive striving that the term 'will' implies is not a fundamental feature of the will, conscious purposive striving is the manner in which we experience it and Schopenhauer chooses the term with this fact in mind (2011, p. 2).

For Schopenhauer, this "blind force" manifests itself in humans as impulse, instinct, and craving towards an insatiable goal, a "will to live" [will, as will to live], a purpose. Clearly, will governs in Schopenhauer's ontology – "a blind unconscious force" universally present in reality. Humans' experience this force as "conscious purposive striving." Again, as with both Hume and Kant, will is conceptualized functionally in what it does, "purposive striving." However, one ransacks Schopenhauer's work in vain looking for the "thing-in-itself" that does the striving.

Schopenhauer inclined a number of thinkers to his views at the end of the nineteenth century. Important among those Schopenhauer influenced was Sigmund Freud, who largely based his philosophic psychology on the pleasure principle: *It seems that our entire psychical activity is bent upon* procuring pleasure *and* avoiding pain*, that it is automatically regulated by the Pleasure Principle* (1935, p. 311, emphasis in the original). "Psychical activity" is "*essentially unconscious*" involving "*instinctive forces*" (1935, pp. 22, 24). Freud follows Schopenhauer to the extent that his will is a striving to achieve an end, with Freud's goal a will to pleasure [will, as will to pleasure] and Schopenhauer's a will to live. Freud explicitly recognizes that this understanding of will is functional, stating that the pleasure principle "subserves a certain function" (1950, p. 144). Freud deploys a lively pantheon of concepts – ego, id, superego, unconscious, transference, repression, etc. – to explain how humans went about expressing their will to pleasure, though he never identified the something that these concepts represented.

An equally significant follower of Schopenhauer, though equally a critic, was Friedrich Nietzsche. He was anti-Freudian in his insistence that, "man does not seek pleasure..." (1901 [1968], p. 273). He was anti-Schopenhauer as to the goal of his will asserting:

> Suppose, finally, we succeeded in explaining our entire instinctive life as the development and ramification of one basic form of the will–namely, of the will to power, as my proposition has it... then one would have gained the right to determine all efficient force univocally as–will to power. The world viewed from inside... it would be "will to power" and nothing else (1886 [1989], p. 36).

Humanity's goal for Nietzsche was not life or pleasure, but power. But he was pro-Schopenhauer in emphasizing the ontological importance of this end, insisting that "...the innermost being is will to power" [will, as will to power] (1901 [1968]); and crying out in the last two lines, "This world is the will to power–and nothing besides! *And you yourselves are also this will to power –and nothing besides!*" (1901 [1968], p. 550, emphasis in the original). As with the other philosophers, will is conceived functionally, in terms of what it does, which is to seek "power – and nothing besides!" Critically, one can search Nietzsche's work and find nothing of the something that makes the will to power.

Hume, Kant, Schopenhauer, Freud, and Nietzsche were not the only thinkers to conceptualize the notion of will, but they were arguably its iconic scholars; they created what might be called a modern problematic of will [will, modern problematic of] (MPW), composed of five similarities and one difference. The first similarity concerned location. Will was something within humans. It was "innermost being." Second, will was understood functionally, as something that innermost being does. The third and fourth shared characteristics pertained to the will's functions. The third commonality was that will produced action, and the fourth was that action was guided to purposes, ends, or goals. Our scholars debated these ends. They could be for pleasure, life, or power; but actions always strove in a particular direction. Before proceeding to the final similarity, consider the main difference. The Enlightenment thinkers imagined will formed action in some way out of knowing. Their post-Enlightenment counterparts had action fashioned out of something(s) other than knowing – be they impulse, craving, or instinct. The MPW conceptualizes that will as something that functions to produce purposive action in humans, through rational or non-rational means.

This brings us to a final commonality, which was an absence, with implications for free will. The MPW philosophers had nothing to say about the something that produced will. This is like saying the heart functions to circulate blood, without examining the organ that is the heart itself. The preceding has a major implication for free will. Scholars for millennia have pondered free will but, if the MPW is some sort of culmination of this tradition, it is clear that scholars cannot judge whether will is, or is not, free, because they literally do not know what it is that might, or might not, be free. Further complexities arise when one begins to examine the concept of freedom as it pertains to will.

Free Will and Critical Structural Realism

Consider the Oxford English Dictionary's definition of "Free" as "…actions, activity, motion, etc.: Unimpeded, unrestrained, unrestricted, unhampered" (1989, p. 158). A test of whether there is *unfree* will [will, restrictions on] is observation that a person's will is impeded, restrained, restricted, or hampered, i.e., whether there are "restrictors" upon will. Two categories of restrictors might be imagined – those that are internal and those that are external to persons. Certainly, it is my will to live forever. Deplorably, the aging process within my antique body will kill me off, if something else does not get me first. Certainly, I have always wanted to be a most brilliant mathematician. Lamentably, I had the lowest of low scores in math testing; something inside of me makes it impossible for me to grasp the simplest of mathematical concepts. Here, then, are two examples of internal restrictors of will. Certainly, it is my will to have a nice, three-bedroom apartment on Gramercy Park in New York City. Regrettably, my income as a professor inhibits realization of this will. Certainly, it is my will to have a more scientific anthropology. Deplorably, this is a time of postmodern anthropology, when my will goes frustrated. Here, then, are two external restrictors of will.

On the other hand, by my sophomore year in college, it became my will to become an anthropologist. Luckily, whatever was inside me intellectually allowed me to become an anthropologist, and the easily accessible funding and the availability of jobs allowed me to realize this will. The intellectual capacity to think anthropologically plus the existence of funding and job opportunities might be thought of as free will's internal and external "expediters." These observations of the vicissitudes of my will lead to the following conclusion: Sometimes the will is free to achieve its goals, sometimes it is not; i.e., there is and there is not free will, whatever will might be. The preceding discussion suggests that two sorts of inquiries are pertinent to a project analyzing will and its *soi disant* freedom. The first is the study of the something itself that is will. The second is discovery of the restrictors and expediters of that will, with the goal of eliminating restrictors and enhancing expediters. Below it is explained how critical structural realism can contribute to this project.

Critical structural realism (CSR) is an epistemology, ontology, and political ethics (Reyna 2002, 2012). Epistemologically, it argues for a realist understanding of knowledge in which science, fortified by elimination of Comtean positivist hubris, is a better tool for knowing about reality than any of the others. Ontologically, the knowledge it seeks is about structures of being and the processes (or logics) of their operation. Further, it is interested in understanding connections between structures: for example, relations between nonhuman and human structures as well as relations between human social organizations and those within individuals. A prominent circumstance of humanity is that people are suspended in webs of structure. So, as Horkheimer put it, this knowledge of these webs of structure is needed "…to liberate human beings from the circumstances that

enslave them" (1982, p. 244). This chapter pertains more to the structural aspect of CSR, because it is concerned to determine the material being that is will.

CSR is interested in systems of structures, that is, with the organization of forms and the interrelationships of these organizations. Two general categories of structures are distinguished – those in I-space and those in E-space. The former are structures internal to the human body and the latter are those external to the body. "I-space" structures include those of the respiratory system, etc. The key I-space structure under examination is that of the nervous system, especially its central organ, the brain. There are two major categories of "E-space" structures – those of human organizations (social systems) and those of nonhuman organizations (natural systems). It is judged that in some way I- and E-space structures are connected and that a central chore of CSR is to discover the nature of these connections. The main claim I want to make is that due to its connections with E-space, and what it does with these connections, the brain, and its activities, is the I-space structure that is the missing something that is the human will. The next section provides a sketch of the something that is the will.

Something Found: The Reflexive Cultural Brain

Thinkers working within the tradition of MPW theorized will functionally rather than structurally as CSR would prescribe. This is not altogether surprising as the structure in I-space that is key to understanding human behavior and cognition from a contemporary perspective, the brain, has been exceptionally difficult to study in operation to find out how its parts work together to generate function. However, this is now being reversed, particularly with the introduction of neuroimaging techniques (e.g., positron emission tomography, magnetic resonance imagining, and magnetoencephalography) that allow observation of the brain as it goes about its business. Consequently, will and the possibility of free will have begun to be explored from the perspective of neuroscience (e.g., Frith et al. 1991; Baumeister et al. 2009; Soon et al. 2009; Sinnott-Armstrong and Nadel 2010; Gazzaniga 2011; Haggard 2011), which clearly indicates that the brain is central to identifying and understanding the something that produces will. Any neuroscientific claim to have found the something missing from MPW should satisfy two conditions: (1) identify the I-space structures that underpin action and (2) reveal the I-space structures that operate to make action purposive. Largely based upon the findings of neuroimaging studies in what follows I propose an account of how the brain is connected with E-space in a reflexive manner that makes action possible, and additionally, I advance the idea that the brain reflects upon E-space in a cultural manner giving action its purposive direction.

The Reflexive Brain and Action

There are numerous approaches to reflexivity. From a CRS perspective, reflexivity is a fundamental attribute of *some* structures, fundamental because it is

a determinant of their powers. Power is any effect(s) of exercises of force, with force understood not narrowly as physical coercion, but broadly as any combination of resources with the ability to cause effects (Reyna 2003). Reflexive structures to varying degrees know "what is" and use this knowledge as a force resource to know "what to do about it." Reflexivity is about power because it is about structures interrogating antecedent E- and I-space events in the present to do something affecting subsequent E- and I-space actions. In this optic, reflexivity is a force resource with the power of binding past, present, and future. How does reflexivity guide action?

Reflexivity, according to Anthony Giddens, "... is generally defined as the monitored character of the ongoing flow of social life" (1984, p. 3). The key term in this definition is "monitored." In CSR, social life is monitored if there is a *monitor*, in the sense of "a device ... for observing or recording the operation of a machine or system..." (Random House Dictionary 1967, p. 925). The "system" monitored is antecedent E- and I-space events. The "observing" is representation of the states of, and plans for, these realities. Observing involves two sorts of representations of E- and I-space events: those describing their states and those involving procedures of what to do about them. In order for individuals to be reflexive, two conditions must be satisfied in their I-space. First, they need an I-space monitoring device able to represent E- and I-space events and to plan what to do about them. Second, they need two "reflexivity extension cords," which – like extension cords – plug individuals' monitoring devices into E-space. The first set of such cords brings antecedent E-space information from reality to I-space to the monitor, in effect plugging E-space into I-space. The second chord brings information from the monitor to make actions that participate in subsequent E-space events. Next it is shown how the human brain working through the nervous system comes complete with a monitoring device and two extension cords.

Wiring, Information, and Representation

The brain is a system of specialized cells called nerves or neurons. There is an estimate of 86 billion neurons (plus at least the same number of support or glial cells) (Azevedo et al. 2009). This system of densely interconnected cells is often called the brain's "wiring." It brings information about E-space into the body, monitors it, and sends it back out as action into E-space. The wiring, then, is both the extension cords and the monitoring device of human reflexivity. It is therefore important to explore this device more fully.

Information in the brain corresponds to electrochemical impulses traveling between neurons. Afferent nerves (those carrying impulses toward the brain from sensory organs) are the extension cord that plugs the brain into antecedent E-space events. Efferent nerves (carrying impulses away from the brain toward the muscles) are the extension cord that plugs the brain into subsequent E-space events through movement. Electrochemical flows within the brain correspond with the operation of the monitoring device that surveys what is out there in antecedent E-space and plan

what to do about it in subsequent E-space. These impulses flow within organizations of neurons variously termed modules, circuits, networks, pathways, or systems. Electrochemical energy moves along all of this wiring in feedback, feedforward, parallel, lateral, convergent, divergent, and hierarchical manners. Systems are collections of interconnected neurons in particular places in the brain performing various functions. They interact with other systems accomplishing higher order functions. For example, the limbic system, primarily concerned with emotions, is in turn connected with the prefrontal cortex, which is in charge of executive control. Together, these two systems form the basis for decision making.

Another important concept to introduce at this point is that of *representation*. Representation in CRS is literally the material reproduction, i.e., *re*-presentation, of something as something else. Our interest is in neuronal representation [representation, neuronal]. This is the representation in neurons of information, i.e., re-presentations of events in an actors' E-space, and what to do about them, in the past, present, and future. Past representation is memory. Present representation can be both present perception and past memories recalled in the now. Future representation is wishes about what to do. Much of the nature of neural representation remains to be learned. However, it is clear that information is represented in the brain as patterns of electrochemical impulses, "…sets of firings in a specific collection of neurons" (Baron 1987, p. 28). This "patterns" are specified by "the rate of firing of each neuron in the collection of neurons bearing the information" (Baron 1987, p. 29). Neurophilosopher Paul Churchland has called these patterns "configurations of synaptic connections," which he believes allow the "general and lasting features of the external world" to be "represented in the brain" (1995, p. 6). Consciously or unconsciously, the patterns of synaptic configurations represent E-space in I-space, either as information about current perceptions, past memories, or future wishes. In this optic, information and representation are not disembodied mental peregrinations. They are the workings of material, neuronal structures. It is time to present how the neuronal flow of information makes the brain a reflexive structure.

The Tripartite Brain

Edward Hundert (1989) proposed an influential tripartite model for the functional organization of the brain. The model divides "the brain into input, central, and output systems" (Hundert 1989, p. 201). The input system performs the tasks of detecting and perceiving. Detection (sensation) and perception provide information about "what is out there" in E-space or I-space to the brain. A man waves and says "hello" from across the street. The waving is transformed into radiant energy, involving light waves, which you can see. The "hello" is transformed into acoustical energy, involving sound waves, which you can hear. The properties of these energies – their amplitudes and frequencies – bear information about the happenings – waving and saying "hello." Energies that contact receptors are termed "stimuli," in the sense that they stimulate the receptors. These respond to stimuli from outside or inside the body and work as transducers, as they transform one form

of energy into another. "Detection" is therefore the transducing of energy bearing information from E-space or parts of I-space other than the brain into electrochemical energy in neuronal I-space, and its transmission along "...afferent pathways to the corresponding ...sensory areas" (Kolb and Wishaw 1998, p. 223).

Information flows through lower and higher afferent pathways to two sorts of sensory areas, one located largely in the posterior (also called the sensory) cortex and the other in the sub-cortical limbic areas. Consequently, two basic types of representation occur: sensory and emotional. Information relayed to the posterior cortices (parietal, temporal, and occipital) is re-presented as perception of sights, sounds, smells, etc. Information flowing to the limbic system (including anterior thalamic nuclei, hippocampus, amygdala, septum, and cingulate cortex, among others) is encoded as emotion. Sensory and emotional information is then projected to the insula, which integrates information on the physiological circumstances of the entire body and from this appears to generate feelings. Current studies suggest the insula to be "...at the very essence of human feelings" (Craig 2004, p. 239). In sum, the input system of the brain first detects and then re-presents E-space as sensory and emotional information. These representations may occur at roughly the same time and, from the actor's perspective, may seem to be reality, with it understood that this "reality" is not reality itself but representations of it. Otherwise put, the input system of the brain tells a person what is the likely state of the world (out there, but also their inner world).

Next, consider the central system where "...the meaning of information" is established (Hundert 1989, p. 201). It is located in the anterior part of the cortex, the frontal lobe, and receives perceptual and emotional information from pathways in sub-cortical regions and the sensory cortex. The most important part of the central system, just behind the forehead, is the prefrontal cortex (PFC), a complex set of areas integrating sensory and emotive representations in order to accomplish "executive control," guidance of thought, and action. The output of the PFC is a new type of information, termed "action messages," specifying what to do about what is that flows along efferent circuits to the posterior part of the frontal lobe, where the output system is located.

Output areas are those that, upon receipt of central system information, perform the task of putting the body into action. They are the premotor and the primary motor cortices. Efferent pathways from the latter transmit action messages to the basal ganglia and the cerebellum from whence they are sent through the spinal cord to the muscles. Two sorts of actions are characteristically performed. The first is practical, where the body's muscles contribute to some human practices in E-space. The second is discursive, where the body's muscles contribute some meaningful message in E-space. Consequently, it can be said that the tripartite brain is one where information from antecedent E-space and non-brain I-space arrives via the input system to the brain's I-space where representations are made. Then, in the central system, meanings of these are interpreted and, on the basis of this, are made into discursive or practical action that reenters subsequent E-space via the output system.

Earlier, discussion suggested that a structure was reflexive if: (1) it had a monitor capable of representing E- and I-space events and doing something about them

and (2) there were incoming and outgoing “extension cords”; the former plugging E- and I-space into the monitor, the later plugging the monitor back into E- and I-space. It has been shown how afferent circuits from the sense receptors to the thalamus, the limbic system, and the posterior cortex transmit information from E- and non-brain I-space events, constituting an incoming extension cord. Then, the flow of this information to the posterior cortex and limbic system gives rise to perceptual and emotive representation of these events, in effect signaling “what is” out there in E-space and non-brain I-space. Next, the flow of these representations to the PFC leads to further flow of information within the various sub-structures of the PFC, and other brain regions to which it is connected, which interpret the procedures concerning “what to do” about these representations, i.e., signaling what to do about represented E- and I-space. Thus, together, the posterior cortex, the limbic system, and the PFC operate as a monitoring device. Finally, the efferent circuits leading from the PFC to the premotor regions, to the primary motor cortex, to the cerebellum, the spinal cord, and onto the somatic motor system effect the implementation of what has been planned in the brain’s monitoring structures, and may be said to be the outgoing extension cord. In sum, the human nervous system contains the monitoring and extension cord structures necessary for reflexivity [reflexivity, and the brain]; and it is in this sense that the brain is a reflexive organ making possible action, satisfying the first of the two conditions necessary for understanding it as “the something” of human will.

One observation might be made at this point: As the brain works through flows of electrochemical energy in neuronal pathways, it is literally more accurate to say that people go with the flow than that they make decisions (rational or otherwise). This raises the question: How does the flow impart purpose to human action? This is the topic of the following section.

The Cultural Brain and Purpose

French phenomenologist Maurice Merleau-Ponty recognized that human action was “intentional,” i.e., purposive, because it “is governed by certain pre-established nervous pathways such that” the goal intended is obtained (1942, p. 7). This section argues that these pathways are cultural ones. The first task of the section is to show how culture has a double structural reality: On the one hand, it is an aspect of social system; on the other, it is embedded within the brain’s neural wiring. The second task is to show how these pathways impart direction to action. Culture and hermeneutics are introduced next; after this, it is hypothesized how the PFC uses culture to impart purposive bias to action.

Culture’s Two Realities

Hermeneutics is the study of understanding (*verstehen*), which comes about as a result of interpretation. One axiom of hermeneutics is: As people interpret,

so they act. The view that the brain is involved in interpretation is old. Baruch Spinoza in the seventeenth century remarked, "men judge things according to the organization of the brain" (in Reyna 2002, p. 96). Emmanuel Swedenborg in the eighteenth century insisted, "…the cortical substance imparts … understanding" (Reyna 2002, p. 89). What reason is there to believe that the brain "imparts" understanding? I argue next this is because the brain is a cultural neurohermeneutic system. Consideration of culture is necessary to make this argument. At its broadest, culture may be defined as that which imparts understanding to actors. But culture may be said to have two distinct manifestations: cognitive and emotive.

Cognitive culture [culture, cognitive] involves understanding of learned and shared "…semantic domains organized around numerous features of meaning…" (Tyler 1969, p. 359). "Semantic domains" are systems of linguistic symbols (words) that constitute informational categories (hereafter simply categories) and are the building blocks of messages. For example, there is the semantic domain of "animal." "Cats" and "dogs" are smaller categories within the larger domain of "animals." Arranging different symbols in grammatically appropriate manners creates a cultural message. Therefore, cognitive culture is, in part, the universe of an actor's informational categories drawn from the universe of categories available in social E-space. Interpretation in this optic is assigning of a cultural category or message to perceptions. When a mother points to a furry, meowing beast and says to her daughter "pussy," her discursive action involves "enculturation," the embedding of discursive culture in another person's neuronal wiring. When a 3-year old then sees a furry creature that meows and exclaims – "pussy" – she has reached understanding and is making an interpretation. Cognitive culture also incorporates other types knowledge present in E-space comprising episodic knowledge, that is, knowledge about events and facts, and procedural knowledge, or knowledge about how to perform a task. These different types of cognitive culture – semantic, episodic, procedural – are encoded as long-term memories in brain regions distributed across temporal, parietal, and occipital cortices as well as in sub-cortical structures (chiefly, hippocampus, amygdala, basal ganglia and cerebellum) (Squire 1987; Fuster 1995).

Cognitive culture comprises both categorizations of "what is" and procedures, or "rules," for dealing with it. Elsewhere (Reyna 2002) categorizations of "what is" have been called "perceptual," because they classify reality, and abstractions about reality, into different symbols. Instructions for dealing with different perceptual cultural categories were said to be "procedural." Cultural systems, thus, have perceptual and procedural aspects. For example, among the Barma of Chad, there is the cultural symbol *bob*. Perceptually, fathers and fathers' brothers are classified as *bob*. Procedurally *bob* are shown *hormo* (respect). Consequently, at an antecedent time, E-space$_1$, a paternal uncle arrives at his niece's hut. He is seen by her and interpreted in her I-space as a *bob*, and at a subsequent time in E-space$_2$, she bows to him, offers water, and offers food, performing the actions consistent with the procedural memory of giving *hormo*.

In addition to perceptual and cognitive, cultural representations can also have an emotive character. Two important properties of emotional memories

are valence and arousal. "Valence" is the dimension of emotion that varies from positive to negative (attractive/pleasant to aversive/unpleasant); while "arousal" is the dimension that varies from no response to intense response (calm to excited) (Schacter 2011). Emotional memories are encoded by an array of structures including the amygdala and other limbic structures like the nucleus accumbens, insula, and orbitofrontal and cingulate cortices (Phelps 2004). Such memories are an actor's emotional culture [culture, emotional], so long as these memories are acquired from and contribute to social E-space.

Cognitive and emotive cultures are closely associated. This is because the cognitive and memory systems "interact in subtle but important ways" so that they "act in concert when emotion meets memory" (Phelps 2004, p. 198). It is far from certain exactly how this occurs, but one way appears to be that the brain remembers reward together with cognitive cultural categories, and cognitive categories are also tagged by arousal and valence. This means that if a cognitive procedural cultural category is retrieved from memory, its emotive cultural representation is also likely to be retrieved. For example, if one is in the cultural category "Republican" in American politics, it has been demonstrated that the opposing cognitive cultural category, "Democrat," is emotionally remembered as something that is pretty unrewarding (Weston 2007). Consequently, when Republicans are obliged to contemplate Democrats, they indulge in "motivated reasoning" involving the operation of limbic structures (including ventromedial PFC, anterior cingulate, insular, and lateral orbital cortices (Weston et al. 2006)) that reflect the negative valence of their memories of Democrats. Dopamine appears to play a role in the association of cognitive and emotive culture by signaling reward: It is released prior to events remembered as pleasant, but absent prior to those remembered as not pleasant (Schultz 2002; Frith 2007). Thus, when a Republican sees a Democrat, there is no dopamine signal with its promise of reward.

Given the preceding, cognitive and emotional cultures might be thought of as a laminate, bonded into a common system of understanding that identifies what is, how it feels, and what to do about it. Returning to the example of the Barma, at an antecedent time, E-space$_1$, a father arrives in a daughter's hut; his daughter sees him. She interprets her father in terms of her cognitive culture as a *bob*. One's action toward a *bob* should follow a particular cultural procedure, that of giving him respect. It can be speculated that the sight of *bob* may trigger a spurt of dopamine compelling the daughter into action. Limbic structures may be variously activated, producing at a subsequent time in E-space$_2$ the performance of *hormo*, leaving her feeling good about it. Here, then, is the significance of culture. It allows the brain to achieve understanding: cognitively of what is and what to do about it; while emotively motivating action consistent with cognitive understanding. Consequently, it is culture that imparts direction to action, and it does so, not because people make decisions, but because they go with the electrochemical flows of their neuronal culture.

The Prefrontal Cortex and Cultural Purpose

A way of beginning to answer how people "go with the flow of their culture" as it is encoded in the brain is to reflect upon the structure of neural wiring. There is an efferent, convergent hierarchy of neurons from the posterior cortex and the limbic system, where cognitive and emotional representations of E-space events are achieved, that terminates in the PFC, and an afferent, divergent hierarchy that leads from the PFC to the motor cortex, the spinal cord, the muscles, and from thence back out into E-space events as action. Something happens within the PFC that "processes" what is going on in E-space and responds by creating action responses, suggesting the PFC is the place in the brain where will to act is generated. Of course, the next query is, how does the PFC "processes" incoming electrochemical flows to make them into outgoing electrochemical flows? At least eight theories had been proposed at the turn of the century to account for PFC function (Wood and Grafman 2003), but none of these specifically addressed the role of culture in PFC function. What follows is a speculative account of how the PFC might employ the culture that it has embedded in its neural tissues to produce action. PFC [prefrontal cortex, structure, and function] anatomy is described first, including its parts and connections with other parts of the brain, and their joint functioning. Next, this information is analyzed to suggest how the PFC uses culture to make action.

The PFC is the foremost part of the frontal lobe. On its sides are the dorsolateral PFC (DLPFC) beneath which is the ventrolateral PFC (VLPFC). More ventrally and medially, behind the eyes, is the orbitofrontal PFC (OPFC). Finally, the ventromedial PFC (VMPFC) is located along the midline and above the OPFC. The different PFC regions are connected with each other. There appear to be "*two parallel*" neural circuits within the PFC (Pochon et al. 2002, p. 5669). The first circuit involves the DLPFC and the VLPFC. It is concerned with *planning* and *executive control of action* (Pochon et al. 2002, p. 5669). The second circuit includes the OPFC and the VMPFC, which deal with emotion and *motivation* (Pochon et al. 2002, p. 5669). The parallel circuits, however, are themselves connected by feedback loops (Fuster 2008). The PFC is as well richly connected with other brain areas. There are also dorsal (upper) and ventral (lower) pathways leading from the posterior cortex to the DLPFC and VLPFC, respectively (O'Reilly 2010). The ventral pathway, largely underpinned by the temporal cortex, has been termed the "what" circuit as it *extracts information relevant for identification and other forms of semantic knowledge*; the dorsal pathway, on the other hand, largely underpinned by the parietal cortex, has been termed the "how" circuit, because . . .*it extracts visual signals relevant for driving motor behavior* (perception for action) (O'Reilly 2010, p. 355, emphasis in the original).

While much debate exists surrounding functional segregation in the PFC (Badre 2008; Botvinick 2008), enough is known to sketch its functional organization. There is agreement that the DLPFC functions as the brain's "working memory" system (Baddeley 1986), which broadly corresponds to conscious thinking about

something. In fact, for some neuroscientists, consciousness itself is understood as "…awareness of what is in working memory" (LeDoux 1996, p. 278). The "work" in working memory, according to Carter, refers to the DLPFC taking "… information from many different parts of the brain–sensory and conceptual– …" which it "'juggles' to come up with ideas for action" (2002, p. 235).

The VLPFC appears involved with language and the retrieval and maintenance of visual and or spatial information. It is thought to be the place where perceptions are put into words. There is also considerable research indicating that it is the place where emotional regulation takes place (Cohen et al. 2012). The VLPFC works closely with the DLPFC. Ward (2010) argues that the VLPFC integrates semantic and perceptual information, stored largely in the posterior cortices, together with emotional information from the limbic system, and that the DLPFC manipulates this new informational composite.

Functional segregation within the PFC is also illustrated by research into inductive and deductive inference. Monti et al. (2007) has made a distinction between "core" and support deduction areas. Both appear "primarily in the left hemisphere" (2006, p. 32). The "core" performs "deductive operations," while the "support" area maintains "content-specific …semantic information" (2006, p. 2). The "core" area appears to be located in the DLPFC, whereas the "support" area seems to be positioned in the VLPFC – with the support area providing the semantic information about which the core area makes deductive inferences. Regarding induction, Goel et al. found that it activates "…a large area comprised of the left medial frontal gyrus, the left cingulate gyrus, and the left superior frontal gyrus" (1997, p. 1305).

The OPFC and VMPFC are emotion and reward centers of the brain (Rolls 2005). As Carter puts it, *Emotions become conscious here*, because it is the place "…where emotions are experienced and meaning bestowed on our perceptions" (2002, pp. 115, 210). Specifically, the OPFC appears to do this by "…decoding reinforcement contingencies in the environment" (Rolls 2005, p. 140). According to LeDoux, people "with orbital cortex damage become oblivious to social and emotional cues, have poor decision-making abilities, and some exhibit sociopathic behavior" (2002, p. 227). This is likely to be the case, because with a damaged OPFC, such persons have lost their knowledge of the reinforcement contingencies in their E-spaces. They are literally cast adrift in a world in which they have been disconnected from what is emotionally beneficial and disadvantageous out there. Their life is, to appropriate a term from Emile Durkheim, neurological anomie. Durkheim's "anomie," articulated in *Suicide* (1898 [1966]) was "normless," not having any rules to know what to do. "Neurological anomie" is the loss of knowledge of the contingencies of reinforcement of everyday life, and so not knowing the emotional rules of what to do. Such life is not so much sociopathic as it is tragic: because persons enduring it are (emotionally) lost in E-space.

Two other brain structures that play an important support role to PFC function are the insula and the anterior cingulate cortex (ACC). A structure where inputs converge from all across the body, the insula, as noted earlier, integrates sensory

and emotional information to generate a representation of the physiological circumstances of the entire body from which a sense of bodily self-awareness (Craig 2009) as well as a sense of agency (Farrer and Frith 2002) emerges. The ACC, on the other hand, appears to have a particularly wide range of functions, including heart rate and blood pressure regulation. Studies of this region suggest that it plays both a "prominent role in executive control of cognition" (Carter et al. 1998, pp. 747–48) and in *emotion/feeling* (Damasio 1994, p. 71). It also "helps to focus attention" (Carter 2002, p. 210), is active in error detection (Carter et al. 1998; Bush et al. 2000), assists conflict monitoring (Holyrod et al. 2004), and is involved with reward-based learning. Attention, error detection, conflict monitoring, and reward learning are interrelated functions. The function of the ACC is therefore likely to detect and monitor actions to respond to errors on the basis of remembered contingencies of reinforcement. ACC and DLPFC operate very close together. Both regions tend to be activated at the same time. However, recent research suggests that the dorsolateral prefrontal cortex functions to "implement control" over action, while the anterior cingulate cortex works in the "monitoring" of the "performance" of action (McDonald et al. 2000, p. 1835).

In sum, neuroscience has revealed that the different parts of the PFC function to provide executive control by processing sensory together with emotional and proprioceptive inputs both from E- and I-space. This processing involves provision of working memory, planning, monitoring, inhibition, switching of attention, and cognitive flexibility. Finally, though much remains uncertain, these operations are about what people conventionally understand as thinking and feeling what is good to do (Fuster 2008).

Where is culture in PFC [prefrontal cortex, and culture] functioning? We know that the PFC plays a central role in people's actions. PFC function underpins feeling and thinking about what is good to do. Culture provides individuals guidelines about what is "good" (and what is not). I would propose culture does this by biasing PFC function in the following manner: To act on a bias is to act in a certain direction, which is another way of saying to act with purpose. Consider that certain events occur in E-space. Information about these events makes its way from E-space to the PFC (through receptor organs, posterior cortices, and the limbic system). The ventral and medial aspects of the PFC (OPFC/VMPFC) determine the reward contingencies of the emotional representations. This information is then transmitted to the lateral PFC pathway where emotional representations become associated with different cognitive, perceptual, and procedural representations. A key point is that both emotional and cognitive representations are cultural: They are acquired from the surrounding cultural milieu. Emotive and cognitive cultural representations are therefore able to bias DLPFC activity whereby on-line (i.e., within working memory) inferences can be made regarding "what is good to do." (All this is accomplished with the support from the insula and the ACC: the former by integrating sensory and emotional information making it available to consciousness, and the latter by screening activity to determine if it follows the action bias established by the DLPFC. If it does not, the ACC signals the DLPFC to re-establish the action bias).

The PFC [prefrontal cortex, as cultural neurohermeneutic system] establishes bias, because it is a cultural neurohermeneutic system, that is, it receives sensory, proprioceptive, and emotional information from E- and I-space, and operates on it based on previous cultural representations across these domains to discover “what is” and “what to do about it.” Such a discovery is an interpretation and, on the basis of such interpretation, the PFC activates the premotor and motor cortices that, in turn, generate action. The implications of the foregoing discussion are threefold: First, the human brain understood as a monitoring device means that it is able to reflect upon events in reality; second, the PFC understood as a biasing device means that it is able to set direction for action giving the brain power to impart purpose on reflection; finally, PFC bias understood as cultural means that purpose is itself cultural.

Free Will and Agency

There are two important implications from the account thus far: The first concerns the modern problematic of will (MPW); the second the very possibility of free will, which leads to a re-appraisal of agency.

A problem with the MPW is the lack of clarity about the something that performs the functions of will, so well articulated by MPW philosophers. The preceding analysis has suggested that a culturally reflexive brain performs the functions of will. Remember that these functions comprise, first, producing action and, second, manifesting purpose, which can be done by rational or non-rational means. It is the brain’s reflexivity that has been shown in the present account to fulfill the function of producing action. In this context, the cultural neurohermeneutic system in the PFC has been proposed to fulfill the function of imparting purpose to action. Finally, the suggestion that the DLPFC/VLPFC and the OPFC/VMPFC establish purpose with both cognitive (i.e., more rational) and emotive representations of events suggests that both sets of MPW philosophers were correct. Will, it seems, operates through both rational and non-rational means.

Consider, however, the implications of the culturally reflexive brain for the possibility of free will [free will, possibility of]. Here I believe many thinkers have been barking up the wrong tree. They want to know: Is there, or is there not, free will? Certainly, prior to any action, the biasing device, that is, the cultural neurohermeneutic system, is *already there* in the PFC (as a result of enculturation), and what is willed is a consequence of the operation of this system. If this is the case, and if freedom is about “unrestricted” action, then, the notion of free will is implausible, because willed action is always restricted by the properties of the brain. The counter argument, “But I am free to change my mind” only means that one set of electrochemical flows in the brain operates, not another, and it is those electrochemical flows which determine will. The retort, “But I am free to change my mind to change my electrochemical flows,” ignores that fact that it is either other electrochemical flows in your brain that change your mind, or events in E-space that change the electrochemical flows in your brain. The sense that you

are free to choose is a phantasmagoric (mis)representation of the reality that you go with the flow of electrochemical messages in your brain.

Furthermore, from a critical perspective, belief in free will [free will, critique of] can assist the powerful in their domination and is actually of little practical interest when seeking to help people in their everyday lives. Consider, first, how the construct of free will assists elite domination. If one believes in free will, it is possible to classify people as “immoral” or “criminal” when they do something that breaks an ethical or moral rule, because they would have been free to will their actions differently. However, many recognize that ethical and moral canons often benefit the powerful. Many poor people steal because of something in their E-space. They are poor. Rich folk classify thieves and the like as “the dangerous sort,” because they – in this example, the poor who steal – have free will and could have avoided a life of crime, thereby avoiding their own immorality – that of tolerating and/or causing poverty – by classifying the poor as immoral criminals.

Let us explore whether the notion of free will has some practical utility when seeking to help people in their everyday lives. It was earlier established that there were forces that influenced will. These were restrictors and expediters that were both internal and external to the human body. This is to say that there were either E- or I-space events that helped humans achieve their will or hampered its achievement. Current structures globally dominating E-space – those of capitalism and imperialism – organize both E- and I-space into two classes – one containing very few actors with enormous external resources to expedite their wills, and the other one containing most of humanity with very few external resources to expedite their wills. This is underpinned by a set of circumstances whereby what those in power do to realize their will often restricts powerless actors’ attempts to realize, in turn, their own wills.

It is at this juncture that the notion of agency becomes relevant. There is a large literature on agency (for a review, see Emirbayer and Mische 1998). The approach suggested by Ortner (2006) is useful for the present argument. For Ortner, agency “is about power” and “the pursuit of (culturally defined) projects” (2006, p. 139) (that is, projects exhibiting will). Thus, “agency” is the power to realize will. Consequently, in the CSR optic, what is important is first to distinguish worthwhile from worthless will, and then to devise methods of expediting the agency of actors striving for worthwhile wills and restricting it for the agency of actors striving for worthless wills. The theoretical notion of a “worthwhile” will [will, worthwhile] is contentious. Practically speaking, however, it seems worthwhile that people have decent places to live, nourishing food, education, and healthcare. The hope is that by strengthening ordinary peoples’ agency, they are given the resources to achieve the power of realizing more of their wills.

Conclusion: By Way of a Eureka Moment

For millennium upon millennium, the search for free will went on, as if it was the Holy Grail of human inquiry. Eureka, the Holy Grail was a phantasmagoric,

and so is free will! This chapter has advanced the idea that the will is something, and that something cannot come from nothing, i.e., that something that is will is either determined within the cultural, reflexive brain in I-space or in the events of social and natural systems in E-space that connect with the brain's I-space. This being the case it is pragmatically argued that it makes critical sense to expand ordinary peoples' agency, the better to give them the power to realize worthwhile wills.

What Is Normal? A Historical Survey and Neuroanthropological Perspective

Abstract

What is considered typical and usual is guided by the cultural framework a person is accustomed to. In the brain sciences, it can easily be forgotten that "normal" and "normality" are not rock solid concepts. Simply acknowledging that "normal" does not have an objective existence is insufficient without also changing scientific practices accordingly. This chapter unpacks why normality has been such a persistent concept for the last two centuries. The concept of normality grew alongside the development of statistical methods and was instrumental in constructing a much maligned concept of "degeneration." Statistics are useful in a wide range of scientific contexts, but detrimental when used as a blunt instrument of measurement to legitimize labels that differentially sort people into subpopulations that augment social inequalities. A rigorous questioning of normality and degeneration ensures an ethical engagement with hypotheses of neuroscience experiments and the implications of research findings. This chapter surveys some of the key historical developments at the origins of the brain sciences to understand some of the biases present today. The language used to classify the world can lead to blind spots that remain

hidden for generations. Rather than searching for a direct localization of human behavior in biological etiology, this chapter advocates a complex localization through mapping distributed agency across intersecting neurobiological, cultural, and environmental processes. Normal might be a value-laden term that has no place in the brain sciences, but a value-free operational conceptualization of the processes of degeneracy may be central to understanding dynamic neuro-cultural systems.

Introduction

Normality is a term that recurs with disturbing frequency in the writings of psychologists, psychiatrists, psychoanalysts, sociologists, and other people concerned with human behaviour.
H.J. Eysenck 1953, p. 177

What is a normal human being?
John Blacking 1977, p. 12

The normal is what you find but rarely. The normal is an ideal. It is a picture that one fabricates of the average characteristics of men, and to find them all in a single man is hardly to be expected.
Somerset Maugham 1938, p. 67

In a telling twentieth century investigation (Rosenhan 1973), eight pseudopatients presented themselves with false symptoms to twelve different medical institutions. Each pseudopatient falsified existential auditory hallucinations to medical staff in order to be admitted into a psychiatric ward. Their falsified self-reports were similar to known psychiatric conditions but were absent from the medical literature of the time. Upon admission, the pseudopatients did not report further hallucinations and behaved sanely and cooperatively. As inpatients, they took notes of their observations and experiences. During their time in various psychiatric wards, they observed that a patient's diagnosis influenced the way staff interpreted behaviors and life histories. Arriving early for a meal, for example, was interpreted as characteristic of the oral-acquisitive nature of a syndrome as opposed to the fact that besides mealtime, there were very few things to anticipate in a psychiatric hospital. For anywhere up to 52 days, despite initial false symptoms and "normal" behavior, psychiatric staff did not detect sanity among the pseudopatients. Paradoxically, other inpatients "recognized normality when staff did not" (1973, p. 252).

Rosenhan's investigation revealed how difficult "normality" can be to detect, most notably by the health professionals of his time. While we may believe that abnormal is defined by identifiable criteria, how is normal defined? Normal and abnormal are mutable concepts that have changed throughout their short history. Anthropologists understand that these terms are relative and defined by cultural experience and social background. What is abnormal in one culture may be considered normal in another. For example, being depressed may be diagnosed as a medical disorder by one authority or regarded as being a good Buddhist by another (Obeyesekere 1985); schizophrenia may be understood as a mental condition by one group or tied to shamanic practices in another (Silverman 1967); dissociative experiences may be pathologized as a neuropsychological disorder in

one community but revered as saintly trance and possession elsewhere (Seligman and Krimayer 2008); sleep paralysis may lead to Sudden Unexpected Nocturnal Death among some peoples but be completely benign among others (Adler 2011). In each case example, anthropologists have observed that a disruption in one social group is benign or healthily integrated in another. Function or dysfunction depends on context.

Normal and abnormal cannot be defined without understanding the beliefs, values, and power structures of a cultural group. Certain cultural beliefs and practices may contain protective mechanisms against some forms of mental illness but open the space for others. As the purveyors of what is normal and what is abnormal, professionals working in mental health and the brain sciences have to recognize their pivotal role in shaping societal values. Defining normality has very real implications for individuals. The opinion of a professional about a person's mental condition can lead to a range of outcomes given the situation: A diagnosis of abnormal can put someone into an institution, let them off a criminal charge, take their children away from them, give them access to support services, delegitimize their status, award them a job, impede them from a raise, distance them from other members of a community, exacerbate existing mental conditions, or even lead to suicide. In cultures where willful deviance is crime and unwillful deviance is illness (Conrad 1981, p. 107), individuals can deny moral, personal, and social controversies by feigning a psychiatric condition that works the mental health system in their favor (Szasz 1962). Political differences can also be undermined by the authoritative power claiming that the deviant position is a result of a mental condition. Medical science reserves the right to confer labels of normality and abnormality, but to what extent are these terms objective and purely descriptive?

Degenerate behavior was once considered sin during religious times, then crime during the rise of the nation state, and now a medical problem with the growing monopoly of biomedical science. Eminent scholars such as Michel Foucault (1965, 1972), Erving Goffman (1961), R.D. Laing (1960), Thomas Szasz (1962, 1963), Ivan Illich (1976), and Ian Hacking (1986, 2001) have argued that our concept of "normal" is a social construct that relies heavily on medical discourse. While the works of these scholars have been highly influential in the humanities, their impact throughout the brain sciences is negligible. Theoretical challenges to the concept of normal in psychoanalysis (e.g., Eysenck 1952) and psychiatry (e.g., Eysenck 1975) have rippled throughout these fields but have not led to tangible change (Treacher and Baruch 1981, p. 120). Interdisciplinary researchers able to translate the importance of critical perspectives from the humanities to contemporary scientific audiences will ensure that a reflexive approach to experimental research and an ethical dissemination of research findings can be carried out. Social constructionist models (e.g., Amundson 2000; Amundson and Tresky 2007; Davis 1995; Hacking 1986; Oliver 1983; Shakespeare 2010) have already proven liberating for communities of people with physical and mental handicaps, because these models demonstrate that marginalizing and stigmatizing classification schemes can be challenged, because labels of abnormal or degenerate are neither purely descriptive nor objective. A sincere engagement with the theoretical import of philosophical work on scientific practice has wide-reaching implications on the lives of individuals and the shape of societies.

H.J. Eysenck, who in the epigraph commented upon the wide imprudent usage of the word "normal," observed that "the same writer frequently employs [the word normal] now in one sense, now in another" (1953, p. 177). He found that the word "normal" was conflated with categories as vastly different as "natural," "ideal," or "statistically representative." When the word "normal" is used to refer to natural processes, Eysenck fittingly reminded his readers that normality and naturalness should not be confused, because what constitutes "natural" is relative to cultural values, beliefs, and standards (pp. 178–181). Eysenck used simple but convincing zoological and anthropological examples to demonstrate the culturally influenced interpretations of what is natural. Zoologists have revealed that what is considered instinctual, innate, and therefore natural in an animal species might be eliminated through altered developmental conditions, and anthropologists have shown that what is considered natural for human kinship relations in one context is considered unnatural in another (Ibid.). The use of the word "natural" to describe animal and human behavior is a social construction.

Surprisingly, Eysenck did not use the same social constructionist argument to counter the conflation of the word "normal" with "ideal." Eysenck's concern with conflating the word "normal" with "ideal" is based upon the claim that the "ideal" is statistically infrequent or not found in a population. While this may be a valid point, the claim that the ideal is rare or absent overlooks that "ideal" is a fabricated notion based on social values and personal attitudes. The ideals of beauty, for example, are highly variable within and across cultures. While amassing wealth and keeping slim may seem attractive in countries such as Australia and the USA, these practices have antisocial connotations in rural Jamaica where plumpness is the ideal (Sobo 1993). Ideals in one culture may be vastly different to the ideals of another. Ideals may even change over a lifetime. What is ideal is as much based on cultural values, beliefs, and standards as the notion of what is natural, and neither term should be allied with what is normal.

When it came to a statistical definition of normality, Eysenck found no issue. This was a huge oversight. Eysenck did not examine the social construction of statistics. He perceived the statistical definition of normality as "perfectly clear, straightforward, and intelligible" (p. 177). However, how can this assertion be trusted when Eysenck conflated the terms "majority" and "average" (Ibid.)? Eysenck also overlooked that any particular average characteristic within a population, such as the average height or average weight, may be exhibited by absolutely none of the individuals from that population. As the statistician Reichmann (1964, p. 121) pointed out, "The average man does not exist. The average applies to a set of data and not to an individual and if the average man could exist he would be such an odd specimen that by his very uniqueness he would deny his own title." The critical approach that Eysenck used to examine what is natural should also be deployed to understand how both the "ideal concept of normality" and the "statistical definition of normality" are socially orchestrated, historically instituted, and culturally constructed.

The walls of institutions that segregated degenerate individuals from healthy populations played an important role in creating a perception of degenerates as a clear-cut, homogeneous, and bounded population

(Adriaens and Block 2013, p. 13). The illusion of homogeneity facilitated the tendency to essentialize mental disorders despite the huge variation in the population of psychiatric patients (p. 6). Seduced by quantitative methods, systems of measurement were deployed to support these views. Privileging some forms of data over others, measurement renders some processes visible and others invisible. Measurement can be used successfully in bioassays, brain scans, and performance tasks, but it is poor at evaluating subjective experience, social variables, and cultural factors. Despite its limitations, measurement has an aura of objectivity. Measurement, however, is limited by what can be quantified. The desire for quantification and objectivity restricts the scientific gaze and is thus a concern for neuroethics.

Measurement does not just quantify the world, it also produces the world. An ethical neuroscience needs to recognize how measurement systems are a mode of power harnessed by those able to use it. Neuroscience has to be reflexive and critical to situate its biases, oversights, and unseen agendas. Anthropology is a useful addition to neuroscience, because anthropologists ask how forms of knowledge are constructed. Anthropology also offers methods to study the subjective and inter-subjective worlds of personal, social, and cultural experience. The benefits are mutual, and a better understanding of neural mechanisms from neuroscience research has an important role to play in the interpretation of cultural meanings and practices. While science makes progress by questioning research findings, anthropology advances by questioning research premises. In a move toward ethical research, the primary objective of this chapter is to unpack statistical notions of normal and historically propagated ideas of degeneration. Combining critical methods from anthropology and neuroscience, this chapter also advocates an operational conceptualization of human behavior as a constellation of distributed processes that each fractionally influence the overall function of neuro-cultural systems.

What Is Normal?

The belief that planets move around the sun in ellipses is owed to an astronomer who spent 6 years battling with a mathematical error of 8 min in the planetary motion of Mars. Many people alive today do not know who that scholar was, and yet if it were not for that scholar, then astronomy may still be imprisoned in a geocentric Ptolemaic universe. With humility, one may ask, how much of our shared reality rests upon the shoulders of people we do not know? Science is built upon the work of countless scholars who have each contributed to our collective knowledge. The history of science provides us with an important check on the historical trends that have led to current beliefs, cultural values, and scientific assumptions.

Planets do not perfectly orbit the sun. They wobble a little. To work out the movement of a planet, astronomers have to work out its location at various points and then average out the measurements. The mathematical methods of astronomy

proved appealing to nineteenth century intellectuals who were looking for new mathematical tools to study and represent human populations. Statistics was once known as political arithmetic (Davis 1995), and early statisticians borrowed concepts from astronomers such as the law of error and applied it to variable characteristics found in human populations (Vertinsky 2002). However, applying the mathematical methods of astronomy to human populations is problematical. A planet is a single moving object. A human population, on the other hand, is composed of a collection of discrete individual organisms each with their own developmental variations. Using calculations intended for a single moving object to represent populations can lead to gross misrepresentations of the data. Calculating the average motion of all the planets in our galaxy, for example, would lead to a nonsensical result. Furthermore, this nonsensical average would in no way be representative of galaxies elsewhere or indeed of all galaxies everywhere.

Despite the flaws, a belief in the regularity of statistical events led to the formulation of the average as being representative of a normal type. By giving "norms" and "normalcy" in populations a measurable character, statisticians like Adolphe Quételet (1835) and Francis Galton (1907) provided nineteenth century bourgeois middle-class values a fashionable scientific justification. The attributes of the average individual were believed to represent "all which is grand, beautiful, and excellent" (Quételet 1842). Deviations from the mean were associated with misshapenness, ugliness, and unfitness. Quetelet's use of the "normal curve" has been described as erroneous and the term "representative" as a bad slip of impartial statistical usage (Vertinsky 2002, p. 101). Although Karl Pearson is said to have corrected Quetelet's language by introducing the term "standard deviation" (Ibid.), statistics no doubt promoted the ranking of individuals within a population and promoted an ethnocentrically and politically skewed idea of what is normal. Statistics reinforced the concept of the ideal and deviant types within a population, and despite some of the most sophisticated advances in statistical measurement, certain basic presuppositions persist today.

An ethnocentric bias means that human groups tend to think of themselves as the rule and not the exception. However, contemporary statistical notions of normal are undermined by the discovery that most behavioral science theory is built upon research that examines an intensely narrow sample of human variation. In an empirical review of the top psychology journals, Henrich et al. (2010a, b) found that most studies disproportionately sample US university undergraduates who are Western, Educated, Industrialized, Rich, and Democratic (WEIRD). Henrich et al. uncovered that in the context of global populations, these WEIRD subjects tend to be outliers on a range of diverse culturally variable traits including visual perception, sense of fairness, cooperation, analytic reasoning, spatial cognition, and memory, among other basic psychological traits. Furthermore, the cultural and developmental environment for WEIRD children is highly peculiar, statistically unusual, and a distortion of species-typical ontogeny. For example, creating a separate room for a baby to sleep is an extremely uncommon practice among world societies. Henrich et al. observe that even though researchers regularly only sample from single subpopulations, they routinely assume that their results are

broadly representative and generalizable despite insufficient evidence. For a range of reasons pertaining to their unique and disproportionate particularities, WEIRD subjects may in fact be the worst population from which to make generalizations. More complete investigations with a comparison of measures across diverse populations would offer more robust representations of human variability. To construct developmental and evolutionary theories of human behavior, brain scientists should be concerned with diversity and variation rather than summarizing data using averages into one exemplar.

Statistics is an influential way of representing population characteristics that plays an influential role in normalizing human behavior. By definition, members of a population fall below the ideal. However, with the introduction of the concept of the average, the ideal was given a form that became an imperative for entire populations. This fabricated concept was rapidly adopted, because it seemingly came from authoritative sources using scientific methods. As the concept of the average spread, it fuelled one of the central forces that shaped the modern world: consumerism (Mason 2010, p. 285). The notion of the average drove consumerism, because it led people to strive for an ideal constantly out of reach. Consumption, once considered a biological disease of wasting (Sanders 1808; Epps 1859), became an accepted cultural label for a way of life.

As Western modes of consumption spread across the globe, so too did Western models of psychopathology. Watters (2010) finds a strong feedback loop between public and professional attention in the spread of Western models of psychopathology around the world. His compelling case-study of anorexia in Hong Kong (pp. 9–63) is an excellent illustration of how professionals, patients, and the public can shape and maintain, albeit unintentionally, Western models of mental illness. One potential consequence of the globalization of Western psychiatry is that it could eventually steamroll local variations in mental illness and perhaps override local buffers against pathology. Fiji, for example, had an extremely low prevalence of eating disorders before the mid-1990s, but just 3 years after the introduction of American television and a cash economy, up to 11.3 % of young girls had developed some form of eating disorder not only through restrictive dieting, but also through using purgatives and self-induced vomiting (Becker et al. 2002). American television and a cash economy therefore seem to have had a normalizing, moralizing, and stigmatizing effect on Fijian society. These forces are all drivers of homogeny, and as they act, they also open the space for the homogenizing treatments of Western neuropsychiatry.

Normalizing behavior is highly visible in social attitudes toward parenthood and child development. Caregivers are constantly subjected to a flurry of conflicting messages as to the best and most effective parenting techniques and practices. These ideal models are often based on little more than folk psychology. A cross-cultural comparison of childhood development among Samoans residing on the island of Upolu (1978–1988), the Matsigenka of the Peruvian Amazon (1995–2009), and middle-class U.S. families in Los Angeles (2001–2004) demonstrated that regardless of highly varied child-rearing practices, human development is fairly robust (Ochs and Izquierdo 2009). Child rearing varied in

terms of bodily orientation between parent and child, social attunement, levels of infant responsibility, the fostering of self-reliance, apprenticeship, and other practices. Consistent across all three groups was the display of moralizing and normalizing behavior. In contemporary society, popular media has taken this moralizing and normalizing behavior in new directions. Nowhere is parental moralizing seen more flagrantly than in product advertisements targeted at anxious caregivers. Discussions about the brain are currently a major space for moralizing discourses (Dumit 1997; Roepstoff 1999, 2002). When the moralizing of brain development becomes commoditized, neuroscience research can be co-opted for capitalist gain. From the marketing of brainfoods to the development of smart drugs, the commodification of neuroscience has ramifications for the types of research that gain financial support and the types of research that remain unfunded. Normalizing behavior may have a lot to do with power structures and group cohesion, but it should be mindfully attended to in the field studies and laboratory experiments of the brain sciences.

In brain imaging, the practice of normalization consists of transferring the scan of an individual's brain from a native to a standard space (such as Talairach or MNI space). This process allows similarities and differences across brains to be identified. However, structurally changing a brain scan to match a reference template wipes out a lot of individual variation. In transforming research subjects into research objects, the representations of each individual scan are mapped to one common co-ordinate system that allows data to be treated as if it were all recorded from the same generalized brain (Roepstorff 2002, p. 161). In other words, tremendous variability in brain activity is translated into the visual simplicity of bright, colorful, and influential brain images. Color-coding of selected statistical parameters has an iconic quality that can create the illusion of stable categories of brain function (Roepstorff 2004, p. 1112).

Images crafted from brain scans make their way from the neuroimaging laboratory to journals, magazines, newspapers, the television screen, and other spheres of public circulation, where they make claims on the personhood of viewers (Dumit 2004). Through these images, people are encouraged to see themselves from a neuroscientific perspective where personhood is reducible to a normalized image of the brain's structure and biochemistry. Standardized brain images portray kinds of brains that define the categories to which individuals belong. Brain images labeled "normal controls," "schizophrenia," and "depression" seemingly illustrate a clear, persuasive, and visually unambiguous difference between normal and unhealthy brains. However, these images obscure the fact that individuals tested as controls because they show no problems on neuropsychological tests can nonetheless exhibit neuropathology in the brain scanner, and conversely that brain scans of individuals diagnosed with a psychiatric condition can surprisingly reveal normal looking brains (Ibid.).

Despite the variability, individuals who submit themselves to experimentation agree to the categories of the researcher and "act as homogenous subjects stereotypically responding to stimuli" (Roepstorff 2004, p. 1108). During analysis stages, variability across research subjects is frequently treated by scientists as

a source of noise and discarded by averaging data (Kanai and Rees 2011). Individual differences, however, can be a rich and important source of information that can be exploited to link brain anatomy to human cognition and behavior (Ibid.). Normalizing processes in scientific experimentation and research dissemination affect the way neuroscientists think about the brain and significantly challenge public understandings of neural, cognitive, and behavioral diversity. Inviting anthropologists to observe, document, and analyze these research dynamics might be a preliminary step in constructing a field of neuroscience that is aware of its pivotal role in shaping personhood and social values outside the laboratory. Developing ways to represent the heterogeneity of research subjects is vital to promoting social inclusion and discontinuing practices that essentialize, stereotype, and stigmatize.

To return to puzzles of our galaxy, it was Johannes Kepler (1571–1630) who first calculated the true motion of the planets. Diverted from his work, he spent the final years of his mother's life defending her against accusations of being a witch. During that period, witch-hunts were a means for the Church to sustain a singular hegemonic worldview. Those accused of witchcraft, like Johannes Kepler's mother Katharina Kepler, were usually guilty of little more than doing things a little differently. When science finally annexed religion to the rights of classifying the natural world, those in power had to navigate new pathways to sustain their hegemony. Natural philosophers started to be called "scientists," a term coined by William Whewell in the 1830s (Sardar 2000), and around 1840, a carpentry term for upright and perpendicular, the "norm," became the root for a constellation of words to refer to the common type or standard (Davis 1995). Terminology may have changed but have hegemonic injustices remained?

What Is Degenerate?

Etymologically, degeneration is simply an alteration in the structure of a preexisting form. From the Latin, *degeneratus*, something is said to degenerate when it "moves away from its genus or type, so that it is no longer general or typical" (Schwartzman 1994, p. 68). Prior to the nineteenth century, the word "degeneration" was used with both positive and negative connotations. The French naturalist Philibert Commerçon (1769), for example, saw degeneration as flowing from natural to civilized, while others used the word "degeneracy" to express their fears of civilization collapsing into chaos (Willard 1673; Sherwill 1704; Warne 1739). With the anxieties of productivist Christian colonial empires, the association of degeneracy with moral decline and negative dilapidation prevailed (Mason 2010).

The second half of the eighteenth century saw the writing of the Virginia Declaration of Rights, the Declaration of Independence, and *Les Droits de L'Homme et du Citoyen*. In a world that was beginning to question established hierarchies, increasingly debating human rights, and in some circles was fighting to hold on to an international slave trade, the political elite turned to the work of a rising class of natural philosophers and physicians as a means to maintain power.

Johann Friedrich Blumenbach, often cited as one of the founders of anthropology, compared different races and argued that people with black, yellow, brown, and red skin color were degenerates from the original white color (Blumenbach 1775). Such theories were readily seized on to legitimate racial inequalities, imperial conquests, and colonial exploitation.

The classification of "degenerate" was used to sideline ethnic groups as well as individuals with abnormal behavior. In the official statistics of the nineteenth century, statistics of deviance began to proliferate around 1820 (Hacking 1986, p. 222). Deviations from the mean "constituted ugliness in body as well as vice in morals and a state of sickness with regard to the constitution" (Vertinsky 2002, p. 101). Degeneracy became more than a word to describe an alteration in characteristics, it gained moral implications and was used to portray defect or decline (Hacking 2001, p. 144). Degenerates were people who were mad, criminals, prostitutes, vagrants, and those who committed suicide (Ibid.). The problem of seeing and classifying degenerates involved reasoning what should be done about them (see Rajchman 1988, p. 102). The growth of statistics of deviance coincided with the abundance of laws about crime and suicide (Hacking 2001, p. 143).

The early brain sciences claimed jurisdiction over the label "degenerate" once a biological etiology of degeneracy was constructed. It was Benedict Augustus Morel (1857) who placed psychiatry within the framework of medicine by arguing that madness was linked to biological alteration. In his seven hundred page volume entitled *Traité des dégénérescences physiques, intellectuelles et morales de l'espèce humaine*, Morel defined degenerations as "deviations from the normal human type which are transmissible by heredity." When the leadership of French psychiatry shifted over to Germany, Morel's ideas traveled quickly to the new center of psychiatric thought. Max Nordau, a German physician, popularized Morel's conceptualization of degeneracy in his widely translated book, *Entartung*, published in English as *Degeneration* (1968[1892]). Eugene Talbot followed suit in his 1898 book, *Degeneracy: Its Causes, Signs and Results*, where degeneracy was vociferously associated with contagious and infectious diseases, destructive behavior, toxic agents, unfavorable climate, mental decline, consanguineous and neurotic intermarriages, juvenile obesity, impure food, arrested development, skeletal anomalies, sensory deterioration, paranoia, hysteria, idiocy, and one-sided genius, as well as social parasitism, moral degradation, and cultural demise (Patrick 1899). An inflected theory of degeneracy that provided biological explanations for crime and mental illness was eventually swept up in eugenic theories. After World War I, degeneration theory became politically vicious and eugenic theory was implemented in the segregation and sterilization of degenerates (Lawrence 2009, 2010).

Degeneracy also became associated with drug use in 1857 (Aurin 2000). Drugs such as opium and marijuana were seen as a cause of degeneracy manifested as delinquency, and a lack of moral character. However, the classification of these drugs was more closely aligned with nineteenth century colonial elitism than with any deleterious physiological effects. Drugs used by the bourgeoisie (e.g., nicotine and caffeine) were seen as good, while drugs used by migrants and the lower classes

(e.g., opium and marijuana) were seen as bad. Subsequent research has shown that the use of illicit drugs is not causally associated with violence (Parker and Auerhahn 1998), the number of deaths in America from alcohol, tobacco, or poor diet and physical inactivity is higher than deaths from illicit drug use (Mokdad et al. 2004), and little evidence supports a link between illicit drug use and psychosis except among copiously habitual adolescent cannabis users who may double their risk of unmasking a genetic predisposition (Arsenault et al. 2004; Hall 2006; Macleod et al. 2004; Wada 2011).

The enactment of drug laws in the twentieth century was strongly linked with the formation of national identity (Weimer 2003) and catalyzed by racial anxiety derived from patterns of migration and social change. Anti-opium laws in America and Australia, for example, were a means to suppress Chinese immigrants during a period of economic recession, social tension, and class conflict (Hoffman 1990; Manderson 1999). Marijuana was criminalized in America not so much because of the effect of the drug but because of its consumption by a marginalized ethnic group, Mexican laborers, who were stereotyped as poor, violent, and criminal (Himmelstein 1983; Nadelman 1989). By using the neurophysiological effects of these drugs as a pretext, authorities were able to further marginalize ethnic minorities. As expected, mass media played a major role in linking illicit drugs with prostitution, poverty, and crime (Musto 1973).

While drugs of the lower classes were criminalized, substances of the elite escaped negative classification. Sugar is a prime example of a substance that through its elitist consumption and colonial trade resisted classification as a drug despite its addictive, health-harming, and drug-like properties (Lustig et al. 2012). Nicotine and caffeine are other examples of substances that for a long time escaped negative labels. Meanwhile, the criminalization of opium, marijuana, and other drugs benefited pharmaceutical companies that no longer needed to compete with unregulated self-medication (Musto 1973). Keeping bioactive substances available only on medical prescription covertly enabled pharmaceutical companies to exploit doctors as their unpaid sales force, while at the same time maintaining high prices for off-patent products that could be manufactured at minimal costs. The authoritative power of medical professionals became two-fold: They defined drug-users as degenerate and only condoned drug use under the strict surveillance of initiated professionals. Too often these classifications were inflected by social biases. In the same way that witch-hunts gave the Catholic Church an opportunity to flex and embolden its power, criminalizing drugs has been used to sustain a political, economic, and social hegemony.

The history of the conceptualization of degeneracy shows how badly diversity and variation has been understood. Using the word "degeneration" often implies that there is a more perfect state, and the term "degenerate" still conjures images of racism reminiscent of a time when difference was despised and misapprehended. The history of racism is a sensitive topic for anthropologists, because their field both founded scientific racism and pioneered the antiracist movement (Hill 1998). In the nineteenth century, the evolution of human societies was conceived as a hierarchical progression from primitive to technologically complex

(e.g., Tylor 1871; Morgan 1877). The blending of this form of evolutionism with the then-accepted ranking of racial groups (see Gould 1981) together with a theory of degeneracy that associated behavioral phenotypes with biogenetic factors (see Pick 1989) fuelled the growth of movements such as eugenics. When eugenicists and racial theorists adopted the concept of degeneracy, phenotypic variations became ranked according to cultural prejudice. Countering these movements were advocate anthropologists such as Franz Boas and his students who found the need to separate the idea of race and culture, and "argue against the unilineal progression of evolutionary stages" (González 2004, p. 19). To counter racism, racial classifications were distanced from biogenetic etiology by arguing that human behavior was conditioned by social and historical circumstances. Evolutionism was pushed to the periphery of some streams of anthropology and with it the concept of degeneracy became inadvertently ignored. Culture became a way to describe human diversity without recourse to biogenetic differences.

Many of the terms of common language, as D'Andrade (1995) observes, blend something about the world with our reaction to it. The term "degenerate" is no exception to D'Andrade's observation. The prevalent historical usage of the word "degenerate" in racial discourse, health disorders, and mental disease highlights normative assumptions of the common "type" and simultaneously demonstrates how difference and diversity have been misrepresented. Hacking (2001, p. 146) distinguishes between degeneracy associated with inherited deviant traits where "alcoholics beget alcoholics, male criminals beget male criminals, child abusers beget child abusers," and allotropic degeneracy meaning "any two or more forms in which a chemical element may exist; carbon, for example, may exist as coal, diamond, or the bucky balls named after Buckminster Fuller." For some nineteenth century behavioral theorists, degeneracy was not strictly uniform and could appear in any form across generations – as alcoholism in one generation, for instance, epilepsy in the next, and crime in the third. While Hacking describes allotropic degeneracy as the inheritance of a disorder with differing symptoms in each generation, allotropic degeneracy in the physical sciences is a neutral description. The many different lattice configurations that an element can form are simply alternative arrangements that exhibit divergent properties.

The attachment of the word "degeneration" to a legacy of moral issues obfuscated the important development of a value-free operational conceptualization of "degeneracy" by George Gamow, a Ukrainian-born American scientist, mathematician, and theoretical physicist (Mason 2010). Gamow contributed to the final solution of the coding problem of DNA by suggesting that the genetic code was degenerate. By degenerate, Gamow meant that some amino acids were recognizable by two or more nucleotide triplets. Degeneracy, as Gamow used the term based on his background in physics, referred to heteromorphic isofunctional elements. In addition to being a recognized characteristic of genetic codes (Goodman and Rich 1962; Reichmann et al. 1962; Weisblum et al. 1962; Barnett and Jacobson 1964; Mitchell 1968; Konopka 1985; McClellan 2000; Frank 2003; Gu et al. 2003), degeneracy thus understood is also known to be a feature of immune systems (Cohen et al. 2004; Fernandez-Leon et al. 2011), respiratory network regulation

of blood-gas homeostasis (Mellen 2010), human movement (Mayer-Kress et al. 2006; Barris et al. 2012), and brain structure (Tononi et al. 1999; Edelman and Gally 2001; Price and Friston 2002; Friston and Price 2003; Noppeney et al. 2004; Figdor 2010). In the brain, for example, different populations of neurons in response to identical external stimuli can produce similar behavioral responses (Noppeney et al. 2004). Gamow's obscure terminology, for many years, demoted the importance of his conceptual contribution to merely the methods sections of science papers. In more recent years, the applicability of the concept of degeneracy has become increasingly acknowledged with neural degeneracy even recognized as foundational to the ability of the brain to acquire cultural skills (Downey 2012).

Degeneracy is an important feature of complex and selectional systems. Without degeneracy, selective processes would not be possible, because, as Edelman and Gally (2001) have established, a population of structurally dissimilar traits is a necessary prerequisite for, an essential accompaniment to, and an inevitable product of the processes of selection. In the brain, degeneracy means that there is a many-to-one mapping between brain areas and behavioral function. "[M]ore than one combination of neuronal groups can lead a particular output, and a given single group can participate in more than one kind of signalling function" (Edelman 1989, p. 50). The example of a neurological lesion that appears to have little effect upon behavior within familiar contexts reveals the presence of degeneracy in the brain (Tononi et al. 1999). Unfortunately, the association of brain areas with the names of famous brain scientists – Broca's area, Wernicke's area, and Brodmann's areas – creates the illusion that each brain area has a singular function and that these areas are fixed and stable. Even though scientists may acknowledge that this one-to-one mapping is not true, many experiments in genetics, the neurosciences, and other biological sciences still subscribe to this essentialist and simplistic model. Mental disorders, for example, are commonly essentialized because "variation is being 'filtered,' to some extent, by particular neurobiological processes" (Adriaens and De Block 2013, p. 115). Essentialism might be a "valuable epistemology," but it is an "ontological error" due to the ascription of natural essences that discord with the phenotypic and genotypic heterogeneity of brain function (Ibid.). The structural variation underlying functional plasticity is a distributed property of complex adaptive systems that has been hidden in plain sight (Edelman and Gally 2001), commonly overlooked because of a reductionist bias (Atamas 2005; Whitacre 2010), and ignored because the term, degeneracy, is misleading (Mason 2010).

Multiple pathways can lead to the same outcome, and locating degeneracy at multiple levels of complexity is a fruitful means of mapping dynamic systems. Taylor (2001), for example, considers acute depression in working-class women in London not simply as the consequence of a biological alteration but as the heterogeneous construction of intersecting variables that take place along the multistranded life course of each individual. In a society in which women are expected to be the primary caregivers for children, the different kinds of causes and their interlinkages include but are not limited to: the loss of, or prolonged separation from, the mother when the woman was a child; a severe, adverse event in the year prior to the onset of depression; the lack of a supportive partner; and

persistently difficult living conditions. These distributed intersecting processes can contribute to the heterogeneous construction of acute depression at a particular moment. Taylor also highlights that the origins of depression are founded upon a variety of different arrangements of biological influences, social structures, and cultural expectations over time. For treatment, Taylor promotes a multi-pronged approach where counselors, social workers, social policy makers, and we could include neuropsychiatrists in his list, can all view their engagement as interlinked, with no particular agent offering a complete solution on their own. In the construction of depression, there are alternative routes to the same end. Outcomes are not endpoints but snapshots of ongoing engagements between intersecting processes. Elements imbricated in one construction process are implicated in many others. From Taylor's description, the situation of acute depression in working-class women in London can be conceived of as a degenerate system in the Gamowian sense. The net flux of a variety of interacting elements in multifarious arrangements can give rise to the same psychological condition of depression. Rather than finding out merely what the brain of someone with depression looks like, a degeneracy-based approach recognizes that a significant amount of genetic and neural processes are open to social and experiential modification.

Due to its association with eugenics in the interwar years and the Third Reich's "Final solution," most mainstream biologists distanced themselves from degeneration theory (Lawrence 2010). Since World War II, the word "degeneracy" has largely disappeared from biological discourse because of the association with harmful ideas that scorned diversity. Ironically, regardless of the best-intended attempts to correct and erase the dangerously conformist behavior that arose from a flawed misappropriation of degeneracy, our productivist and consumerist lifestyle has still nonetheless managed to replace diversity with standardization. The negative controls of Nazi murder and mutilation have been substituted by the positive controls of materialism and consumerism as the drivers of homogeny. Riefenstahl's NAZI propaganda film, *Triumph des Willens* (Riefenstahl 1935), could be likened to modern day MTV filmclips, and the choreographed movement choirs, called *Gemeinschaftstanz*, of the Ministry for Enlightenment and Propaganda (Kew 2001, p. 78) could be likened to popular contemporary aerobics styles such as Zumba, Body combat, and Tai-Bo. Selectively breeding the ideal body is unethical, but marketing products that supposedly assist individuals attain the perfect body is demonstrably profitable. Though categorizations of normalcy and degeneracy may be dismissed in rhetoric and are often pilloried for their reactionary, racist, and eugenicist subtexts, the notion of the standard type maintains a strong, subliminal, and enduring influence in prescriptive modes of education, medicine, and popular culture. Old words may be shunned, but normative practices persist nonetheless. Political correctness might shape our vocabulary, but it does not necessarily stop discriminative practices or standardizing processes from being realized. Distinguishing the history of degeneration employed by medical scientists (Lawrence 2009, 2010) from degeneracy as defined in systems biology (Mason 2010) is the first step toward understanding the heterogeneous construction of human experience.

Brain lesion and functional neuroimaging studies are showing that a particular function can be sustained by degeneracy within one brain and in degeneracy over subjects, i.e., cognitive performance can be produced by multiple systems within one subject and by different systems in different subjects (Noppeney et al. 2004). Degeneracy distributed across a population of individuals suggests that degeneracy operates at the cultural level. Anthropologists recognize that the key to understanding human cultural diversity is the study of how cultural traits persist and change over time (Mulder et al. 2006). The operational framework of degeneracy is a flexible conceptual tool to map the transmission and transformation of cultural traits over time. Describing degeneracy at the neural level and the cultural level might offer anthropologists and neuroscientists a shared vocabulary. If anthropologists working at the cultural level and neuroscientists working at the neurobiological level can find a common language, then they will be able to contribute collaboratively to a holistic and ethical study of the diversity of human experience.

Conclusion and Future Directions

We live in an increasingly brain conscious society. It is not surprising to hear someone describe their mood in terms of serotonin levels or a rival's behavior in terms of a neuropsychological condition, or to ask a friend who is acting silly if they have forgotten to take their medication. Are we becoming neurocentric? And if we are, what are the consequences? Without understanding the cultural lens through which we prioritize mental processes in explanations of human behavior, we are likely to overlook major biases in our thinking. Beyond a mere biography of language terms, this chapter has charted social and political dimensions entangled in the way science categorizes and classifies the world. Combining the epistemology of neuroscience with the self-reflexive methods of anthropology is the first step toward what Domínguez D. et al. (2010) have termed "a humanistic science." If technological developments are not accompanied by advances in our conceptual tools, then we will still be stuck in the age of witch-hunts, which will distract us from the real work of studying human brain and behavior.

The brain sciences occupy a capitalist post-Cartesian world where connecting the mind and the body has become a commodity that can be sold. Substances and body practices concerned with brain function are an open target for commodification. Food companies, for example, are constantly trying to fashion products high in omega-3 and with a low glycemic index that trigger gustatory reward mechanisms and simultaneously enhance mental performance. Pharmaceutical companies are explicitly in the game, and so too is online gaming, public media, and the self-help industry. With increasing attention paid to intelligence, health, and personal achievement, what you consume is on the sights of suppliers. By encouraging the public to conceptualize brain function according to a scientific discourse of normalcy and degeneration (in the moralistic sense), the mental health industry can simultaneously market itself as one of the good guys while improving sales. With due acknowledgment to the practitioners who deliver empowering services to vulnerable populations,

professionals must also be concerned for those individuals who feel inadequate because of cultural values promoted by a mental health industry that creates more categories of abnormality than it knows how to heal. Neuroanthropological perspectives that situate experimentation and medical practice within social settings, cultural values, and individual experience can facilitate in building ethical scientific practices. Placing an emphasis on diversity and shifting degeneracy from a direct localization in brain function to a distributed localization at intersecting neural, cultural, and environmental levels will play a key role in shaping equitable practices.

Professionals in the brain sciences can help to dispel myths about normalcy and degeneration at all levels of society. For over 150 years, medical professionals have claimed jurisdiction over the identification of degeneration irrespective of their capacity to redress the condition effectively or the social consequences of the label. While scientific thinking in the West provides protective mechanisms against culture bound syndromes found elsewhere, such as koro (a syndrome found in places like Northeast India (Sachdev 1985), South Celebes (Van Brero 1897), and remote Guangdong, China (Wen-Shing et al. 1988), involving the belief that one's genitals are retracting) or latah (found among some people in Indonesia and Malaysia (Bakker et al. 2013), latah is a heightened startle response with tic-like behaviors), to what extent has science weakened our resistance to culture bound features of schizophrenia, depression, and dissociative disorders? A neuropsychological substrate is undoubtedly at play, but locating degeneration in the biology of individuals dismisses multiple levels of intersecting variables and the manifold pathways of potential intervention. Adopting a value-free operational conceptualization of degeneracy allows us to model variable factors at multiple levels of complexity (Mason 2010). Neuroscience models based on degeneracy, not normalcy, combined with a particularistic approach will provide a more holistic and more humanistic account of the diversity of cultural experience and the neural bases of that experience (Domínguez et al. 2010, p. 141; Domínguez 2007). Furthermore, taking a self-reflexive approach and questioning the most basic assumptions of our scientific culture might serve to de-stigmatize diverse mental conditions, open new avenues of treatment, and cultivate a better-integrated society.

Neuroethics and Identity

Neuroethics and Identity

Abstract

Identity is a concept of pivotal importance in neuroethics, especially in relation to recent and emerging advances in neuroscience that promise to effectively treat a wide range of motor and psychological disorders. A persistent worry is that modern neurotechnologies (including electroconvulsive therapy, psychosurgery, neural stimulation, psycho-pharmaceuticals, and stem cell transplantation) may negatively affect personal identity. This introduction briefly summarizes the papers in the section "Neuroethics and Identity," each of which addresses a particular facet of identity as the concept is, or might be, applied in neuroethics. In an effort to clarify the diverse understandings of the concept, the introduction concludes with summary statements on numerical identity, forensic identity, practical identity, narrative identity, and extended identity.

Introduction

In contemporary Western political and ethical theory, persons are generally thought of as autonomous, rational, self-aware, self-reliant, and self-interested beings.

Psychological or cognitive changes that alter these features of persons, be they a result of illness (such as depression, dementia, or obsessive compulsive disorder), or a result of brain interventions (such as psycho-pharmaceuticals, neurosurgery, or neurological stimulation), are thus morally salient. Indeed, changes that dramatically alter personality, behaviors, beliefs, and perceptions raise serious concerns about threats to personal identity, especially when those changes result from novel treatments or enhancements. There is not as yet, however, widespread agreement in the neuroethics literature on the meaning and scope of the concept of identity. While narrative approaches to identity appear to have significant appeal, the proponents of narrative identity offer different interpretations of the concept. The five chapters in this section on identity (four by philosophers and one by a legal scholar) elucidate some of these different perspectives.

Overview

The opening chapter by Catriona Mackenzie and Mary Walker carefully outlines at the outset, three distinct concepts of identity – numerical, practical, and narrative identity. As summarized by the authors, numerical identity usefully addresses questions of metaphysical essence, individuation, reidentification, and survival. Answers to these questions typically focus on theories of psychological continuity (with a particular focus on reason and self-awareness), or on theories of bodily or biological continuity (with a particular focus on biological life). With practical identity, the focus is on one's normative self-conception; identity is a concept that captures one's defining beliefs and values, motives, emotions, and so on. With narrative identity, the focus is on self-constitution over time.

This chapter has two discrete aims. The first aim is to clarify the concepts of identity, authenticity, and autonomy in order to better understand and evaluate the empirical data available from first-person reports of dramatic personality changes following neurotechnological interventions – changes that are experienced as either disorienting or liberating. The second aim is to show that a relational, narrative approach to identity and autonomy provides a more useful normative framework than an ethics of authenticity for assessing "the ethical implications of changes in identity arising from the use of neurotechnologies" (this volume p. 382). Mackenzie and Walker identify three problems with authenticity as the frame of reference for discussions of identity. First, the authenticity framework is conceptually misleading insofar as it fails to carefully demarcate authenticity as self-discovery from authenticity as self-creation. Second, each of these conceptions of authenticity is flawed insofar as authenticity as self-discovery wrongly presumes a static inner life and authenticity as self-creation blurs an important distinction between identity and autonomy. Third, both of these conceptions of authenticity fail to properly account for the dynamic, relational nature of identity. This chapter ends with a strong endorsement of a relational and narrative understanding of identity and autonomy.

The chapter by Marya Schechtman examines the identity question from a narrative perspective with reference to the illness of Dissociative Identity

Disorder, a condition where two or more distinct personalities/identities are alleged to share one body. In 1996, Schechtman published *The Constitution of Selves*. In this book, she criticizes traditional philosophical understandings of personal identity that focus on questions of reidentification and, having done so, she makes a positive contribution to the literature on identity in developing her influential Narrative Self-Constitution View of identity. According to Schechtman, "self-constitution must be part of a viable account of identity." (95) Accordingly, persons constitute themselves by developing an autobiographical narrative – a life story – "through which they experience and act on the world" (this volume p. 396). Their autobiographical narrative allows them to make sense of both past and anticipated events and experiences.

Initially, one might think that the Narrative Self-Constitution View of identity could allow for the possibility of more than one person in one body, as each alter could have something like a personal narrative (a distinct life story). Schechtman insists, however, that the autobiographical narrative of each alter would likely be somewhat deficient. She writes: "The fact that 'someone else' has controlled the body to which an alter 'returns' after a hiatus makes the standard kind of person-constituting narrative impossible" (this volume p. 399). As an alternative, Schechtman posits a plausible narrative of a single person with a rare disorder who is psychologically fragmented and in need of reintegration. She does not, however, suggest this as the definitive answer to the question of whether there can be more than one person in one body. Her aim in this chapter is simply to highlight the complexity of Dissociative Identity Disorder in relation to both issues of moral and criminal responsibility.

The next chapter, by Thorsten Galert, examines the impact of brain interventions on personhood and personal identity. The focus of this chapter, unlike the previous chapters, is on the identity (and other) effects of brain interventions, not the effects of illness on identity. For illustrative purposes, Galert focuses on case reports involving Deep Brain Stimulation for Parkinson's Disease. Deep Brain Stimulation is an invasive neurotechnology known to result in important and sometimes quite dramatic psychological changes.

At the outset, Galert distinguishes changes in personhood from changes in personal identity. On his view, a person's existence can properly be described as coming to an end if one of the prerequisites for being a person is lost as a consequence of a brain intervention (as when, for example, the effects of Deep Brain Stimulation undermine autonomy to such an extent that a person can no longer be held responsible for her actions). Most times, however, brain interventions that result in psychological changes merely result in personality changes, and only a subset of these personality changes are profound or significant enough to qualify as changes in personal identity.

Galert uses the distinctions between psychological changes, personality changes, personal identity, and personhood to make explicit the normative implications of the different ways in which the concept of personal identity is used in the neuroethics literature. If this concept is understood in numerical terms, then it follows that a change in identity means that a person "disappears." Understood in this way, a change in personal identity resembles a loss of personhood insofar as either consequence can only be considered a grave risk of brain interventions. On the other hand, if personal

identity is understood in narrative terms, then it is possible to describe changes that result from brain interventions in positive terms (perhaps especially when such interventions aim to change a person's identity for the better). Reasoning along these lines, Galert suggests that narrative accounts of identity (as posited by Schechtman and others) may be helpful in making sense of personality changes.

The fourth chapter by Rob Wilson and Bartlomiej Lenart represents a potentially dramatic shift in approaches to identity. The authors take as their starting point the important role that memory plays in psychological accounts of personal identity and in the extended mind thesis. On psychological accounts of personal identity, what matters is psychological continuity over time, hence the important role of memory. According to the extended mind thesis, memory can be distributed between the body and the world, a thesis supported by our increasing reliance on cognitive tools and structures outside the body (e.g., pen and paper, calculator, computer) in the activity of remembering.

Building on the extended mind thesis, Wilson and Lenart argue that narrative memory (a defining feature of psychological accounts of personal identity) need not be limited to individualistic recollection but can "incorporate the world beyond the individual" (this volume p. xxx). One example of this is cognitive offloading, where people rely on external environmental factors to lighten internal memory load. Other examples of how memory is physically extended beyond the body involve shared or co-constructed memories between two or more individuals, where the task of remembering is distributed. In the later instance, individual narratives constitutive of personal identity are entwined with collective remembering.

The relationship between individual narratives and collective remembering suggests to Wilson and Lenart that tracking a person's psychological identity over time may involve many minds, and that sometimes "identities are realized in the collective remembering of others" (this volume p. xxx). One implication of this extended account of identity is that even individuals with cognitive limitations that prevent them from tracking their own identities can nonetheless have extended identities in virtue of the remembering of others.

The final chapter is by Jennifer Chandler, a legal scholar with a particular interest in neuroscience. Her chapter examines issues at the intersection of neuroscience, personal identity, and law, with reference to two discrete theoretical approaches to personal identity – numerical identity and narrative identity.

In discussing numerical identity, Chandler notes that in assigning responsibility for criminal activity, the law typically relies on physical evidence (such as eye witness reports, fingerprints, and DNA) to identify the perpetrator(s), having assumed a one to one correspondence between the psychological and physical being. But what if the accused claims to have Dissociative Identity Disorder where there is more than one psychological being in one physical person? And, what if the host or dominant identity claims that an alter identity is responsible for the alleged crime? Is Dissociative Identity Disorder a single disordered identity (a problem with meta-memory functioning), or are there multiple distinct identities within one body (a fragmentation of memory)? How should the law respond?

Setting aside this example where numerical identity may be relevant in law, Chandler moves on to a discussion of narrative identity and draws the reader's attention to three distinct issues. The first issue concerns legally coerced consent to "self" changing brain interventions (interventions expected to alter cognitive functions and personality attributes). On occasion, the law pressures convicted criminals to accept treatment aimed at changing personality and behaviors (e.g., anti-androgen drug therapy for sex offenders) in exchange for a specific legal advantage (e.g., avoiding incarceration, or receiving a reduced sentence). The second issue concerns the disclosure requirements for informed consent to brain interventions that may alter the "self." A treatment intended to alter memory (e.g., propranolol for post-traumatic stress disorder (PTSD)) might also undermine a person's ability to testify in court about the event that caused the PTSD. Should this nonmedical risk of treatment be disclosed during the consent process? The third issue concerns legal responsibility for behaviors committed after "self" changing brain interventions. Imagine a patient who engages in criminal activity while under the influence of brain stimulation. Should the treating physician bear any legal responsibility? The chapter does not aim to authoritatively answer the questions posed, given jurisdictional variation in the applicable laws, but rather highlights the complexity of some of the issues at the intersection of neuroscience, personal identity, and law.

Conclusion and Future Direction

In closing, this section on personal identity explores various understandings of the concept, including numerical identity, forensic identity, practical identity, narrative identity, and extended identity. Numerical identity typically focuses on psychological continuity and/or biological continuity. Forensic identity underscores the importance of continuity of consciousness and highlights the relevance of having moral responsibility for one's actions. Practical identity depends upon one's normative self-conception in addressing questions about the self, about who one is. It captures those beliefs and values, motives, emotions, etc. that one perceives as defining one's nature. With narrative identity, the focus is on a self-constitution over time in creating one's life story, a story that must nevertheless meet certain external constraints, as not all stories qualify as identity-constituting narratives. And finally, with extended identity, the claim is that the psychological states constitutive of the identity of a person over time can extend beyond that person's body. An important, putative consequence of this understanding of identity is an expansion in the range of persons who can be recognized as having personal identity to include those with even extremely limited cognitive capacities.

Each of the contributors to this section on identity review one or more of these perspectives showing how each has something to say about the metaphysical and normative significance of personal identity when changes manifest as a result of illness or brain interventions. In different ways, all of the contributors embrace a dynamic understanding of identity and, as such, are less sympathetic to claims about threats to identity that are grounded in assumptions about authenticity.

23 Neurotechnologies, Personal Identity, and the Ethics of Authenticity

Abstract

In the recent neuroethics literature, there has been vigorous debate concerning the ethical implications of the use of neurotechnologies that may alter a person's identity. Much of this debate has been framed around the concept of authenticity. The argument of this chapter is that the ethics of authenticity, as applied to neurotechnological treatment or enhancement, is conceptually misleading. The notion of authenticity is ambiguous between two distinct and conflicting conceptions: self-discovery and self-creation. The self-discovery conception of authenticity is based on a problematic conception of a static, real inner self. The notion of self-creation, although more plausible, blurs the distinction between identity and autonomy. Moreover, both conceptions are overly individualistic and fail sufficiently to account for the relational constitution of personal identity. autonomy can incorporate the more plausible aspects of both interpretations of authenticity, while providing a normatively more illuminating theoretical framework for approaching the question of whether and how neurotechnologies threaten identity.

Introduction

Developments in the cognitive neurosciences are rapidly expanding scientific knowledge of the structures and functions of the brain. They are also enabling the development of a range of neurotechnologies that directly manipulate the brain in order to improve patients' functioning or capacities, or alter mood, cognition, behavior, or personality. These neurotechnologies include electroconvulsive therapy (ECT), psychosurgery, neural stimulation, and psychopharmaceuticals. For example, neural stimulation, which includes transcranial magnetic stimulation and deep brain stimulation (DBS), can be used to treat a range of disorders, including motor disorders associated with Parkinson's disease (Schupbach et al. 2006), severe depression and, potentially, addictions, and other compulsive disorders (Pisapia et al. 2013). Psychopharmaceuticals, such as antidepressants, antipsychotics, and medication for attention-deficit hyperactivity disorder (ADHD), can also bring about global changes to functioning, mood, and behavior.

In the recent neuroethics literature, there has been vigorous debate concerning whether the use of such neurotechnologies is ethically problematic because, even if they improve the person's condition, they may change, or threaten, his/her identity. These concerns have been brought to the fore by empirical studies documenting such changes and patients' attitudes toward them. Carl Elliot, citing one such study, recounts the story of a neurologist for whom dinner party invitations triggered episodes of acute social anxiety (2003, pp. 55–56). After several weeks on an antidepressant, the patient describes himself as feeling "'like a new person'. He felt more confident, and began to enjoy initiating conversations with other people" (Elliot 2003, p. 56). On the other hand, in a study by Bolt and Schermer, a patient taking medication for ADHD reported that the treatment altered his personality in ways he disliked, making him cynical and indifferent (2009, p. 106).

Similar descriptions of changes to identity, character, and mood are reported in studies of patients treated with DBS for Parkinson's disease. A study by Schupbach and colleagues of 29 patients found that despite improvements in motor control, a number of patients experienced significant posttreatment difficulties with social adjustment (e.g., due to changes in relations with their spouses and families or in their professional lives) and self-perception, including with respect to body image (Schupbach et al. 2006). A female journalist who had hoped that DBS would enable her to get back to her life and renew her projects was reported to have lost interest in her work, her family, and her life after the treatment. Her loss of "vitality" appears to have been related to the loss of the goal that gave meaning to her life: fighting her disease. She is quoted as describing this change in the following

terms: “Now I feel like a machine, I’ve lost my passion. I don’t recognize myself any more” (Schupbach et al. 2006, p. 1812). Another patient, who described himself as having been “asleep” during the years of his illness, felt a renewed sense of confidence, energy, and interest in life as a result of the treatment. This change in the patient’s sense of self was, however, a source of marital conflict. His wife, who described them as “a perfect couple” when he was sick, seemed to interpret his current behavior as self-deceived: “‘Now, he wants to live the life of a young man, go out, meet new people,’” leading her to bemoan “‘I would rather he be like he was before, always nice and docile!’” (Schupbach et al. 2006, p. 1812).

Much of the ethical debate concerning the implications of these kinds of changes to identity has been framed around the concept of authenticity. This is no doubt due to Elliot’s influential critique of the increasing use of enhancement technologies, which he characterizes as quests for authenticity (2003). Elliot’s account of the ethics of authenticity is derived from Charles Taylor’s analysis of the sources of modern conceptions of identity (Taylor 1989; Elliot 2011). Just as Taylor understands his project as tracing the genealogy of the modern self, so the primary aim of Elliot’s work is cultural diagnosis: to disentangle “the complex relationship between self-fulfilment and authenticity, and the paradoxical way in which a person can see an enhancement technology as a way to achieve a more authentic self, even as the technology dramatically alters his or her identity” (2003, p. xxi). However, at times Elliot seems to move beyond diagnosis to endorse an ethics of authenticity, even if he is critical of enhancement technologies as means to achieve authenticity.

The language of authenticity has subsequently been taken up in the neuroethics literature and has become central to philosophical debates concerning the ethical implications of neurotechnologies, whether used for the purposes of treatment or enhancement. For example, David DeGrazia (2000, 2005) and Neil Levy (2011) appeal to the ideal of authenticity in defending the use of psychopharmaceutical enhancers, arguing that they can enable a person to be (or become) who he/she most wants to be. In the context of the use of DBS for treatment purposes, Felicitas Kraemer (2011b) notes that experiences of authenticity and alienation differ for different patients. Nevertheless, she suggests that “the concepts of authenticity and alienation are useful heuristic tools not only for a better philosophical understanding of the patients’ experience of DBS, but also, in some cases, the use of these concepts can even lead to a re-evaluation of the treatment and its side-effects and should, therefore, contribute to future reflection on DBS” (2011b).

Empirical studies of patients’ first-person phenomenological experiences of, and attitudes toward, identity changes arising from direct brain interventions are crucial for understanding some of the ethical issues raised by these neurotechnologies, whether used for purposes of treatment or enhancement. It is also true that patients’ first-person descriptions of these changes sometimes use language that seems to evoke the notion of authenticity. However, in our view the ethics of authenticity provides a misleading normative framework for assessing the ethical implications of changes in identity arising from the use of neurotechnologies. This is not merely because, as many in the literature have noted, there are significant differences

between the experiences of different patients with regard to whether neurotechnological interventions appear to enhance or hinder some sense of authenticity. Rather, it is because the ethics of authenticity, as applied to neurotechnological treatment or enhancement, is conceptually misleading. The notion of authenticity is ambiguous between two distinct and conflicting conceptions: self-discovery and self-creation (Levy 2007, 2011). The self-discovery conception of authenticity, as articulated in the neuroethics literature, is based on a problematic conception of a static, real inner self. The notion of self-creation, although more plausible, blurs the distinction between identity and autonomy. Moreover, both conceptions are overly individualistic and fail sufficiently to account for the relational constitution of personal identity.

The aims of this chapter are therefore twofold. First, in order to understand what might be at stake in some of the first-person patient reports of disorienting, or liberating, change consequent upon various neurotechnological interventions, it is important to clarify and distinguish the concepts of identity, authenticity, and autonomy. Second, we seek to show that the ethics of authenticity is misleading and individualistic. We also propose that a relational, narrative understanding of identity and autonomy can incorporate the more plausible aspects of the self-discovery and self-creation notions of authenticity, while providing a normatively more illuminating theoretical framework for approaching the question of whether and how neurotechnologies threaten "identity." It is important to clarify that the aim of the chapter is not to undertake first-order ethical analysis of specific neurotechnologies nor to weigh into debates about treatment versus enhancement; rather, it is to raise questions about the philosophical adequacy of framing these debates around an ethics of authenticity.

Section "Three Concepts of Personal Identity" distinguishes between three different concepts of personal identity (numerical, practical, and narrative), in order to clarify the sense of identity that is at stake in the concern that direct brain interventions might pose a threat to identity. Section "The Ethics of Authenticity: A Relational Critique" begins by explaining how this concern has been framed in debates about the ethics of authenticity, drawing on Levy's (2007, 2011) distinction between self-discovery and self-creation. We then explain why both conceptions of authenticity are premised on individualistic assumptions about identity, and why the notion of self-creation conflates identity and autonomy. In developing this critique, we propose a relational and narrative approach to identity and autonomy as an alternative to the ethics of authenticity.

Three Concepts of Personal Identity

When a person undergoes dramatic change of a kind that prompts the person or others to say "She is [or "I am"] not the same person any more," there are several ways of interpreting the kind of identity at stake. Drawing on the philosophical literature on personal identity, we can distinguish three concepts of identity that might be relevant to interpreting such statements: numerical, practical, and narrative.

Numerical Identity

Concepts of numerical identity seek to respond to questions concerning metaphysical essence, individuation, reidentification, and survival. Questions of metaphysical essence are concerned with the criteria for determining the essential features of the kind "person," that is, those features that distinguish persons from nonpersons. Questions of individuation are concerned with the criteria for determining what makes an individual person metaphysically distinct from other persons. Questions of reidentification are concerned with the criteria for determining what makes an individual numerically the same person despite qualitative changes over time or under different descriptions. Questions of survival are concerned with the criteria for determining when an individual person can be said to survive or to have ceased to exist. These questions are interconnected. How each question is answered will constrain possible answers to the other questions.

Philosophical debates concerning numerical identity are broadly divided into two kinds of answers to these questions. The first kind of answer, proposed by psychological continuity theorists, derives originally from John Locke (1975). Its most well-known contemporary exponent is Derek Parfit (1984). Psychological continuity theorists claim that what essentially characterizes the kind "person" is the psychological capacities characteristic of personhood, in particular capacities for reason and self-awareness. What individuates each person, as a metaphysically distinct entity, is their distinctive consciousness or mental contents; and what makes an individual the same person over time is continuity of this consciousness or mental contents. That is, what makes a person (A1) at one time the same as another person (A2) at a later time is that the right kind of psychological relations hold between them, in particular that A2 remembers doing or experiencing things done or experienced by A1, acts on intentions formed by A1; exhibits traits of character, personality, and temperament that are sufficiently similar to those of A1; and so on. A person survives on this view just so long as these relations of psychological continuity obtain.

Although psychological continuity theories seem intuitively plausible, much of this plausibility derives from our practical and evaluative interests in personal identity. As Marya Schechtman (1996) argues, these interests are connected to concerns related to moral responsibility (80–81), self-interested concern (83–85), survival (87–89), and compensation (86). We suggest that these are the kinds of interest that underlie concerns about whether direct brain interventions threaten identity, and as we explain below, we think that these concerns are better captured by practical and narrative approaches to identity. Moreover, as David DeGrazia argues, because numerical identity is concerned with the logical relation of identity, psychological theories face difficulties explaining the sense in which individual human persons are numerically identical to individual human biological organisms (2005, pp. 31–33, 45–46). The psychological continuity view implies, for example, that a person is not the same numerically distinct individual as the early stage fetus from which he/she developed, since no relations of psychological continuity hold between the person and the fetus. It also implies that an individual with dementia

who has very few remaining psychological connections with the person he/she once was, or a person in a persistent vegetative state (PVS) who has no psychological connections, does not survive as the same numerically distinct individual. Since the biological human organism persists in all these cases, the psychological continuity view thus seems to imply, problematically, that the person and the human biological organism are metaphysically distinct entities.

The second kind of answer, proposed by bodily or biological continuity theorists, rejects the claim that human persons are essentially persons (to use DeGrazia's terminology) and holds that, as far as metaphysical or numerical identity is concerned, we are essentially biological organisms, that is, human animals (Olson 1997; DeGrazia 2005). What individuates each human animal is their distinctive biological makeup, and what makes an individual the same over time is sameness of biological life. So long as this biological life survives, the human animal survives. On this view, personhood, rather than being essential to human persons, "represents merely a phase of our existence" (DeGrazia 2005, p. 49). So, the early stage fetus and the person he/she later becomes are numerically identical by virtue of the fact that they are the same continuing human animal. Likewise, the person who suffers dementia and eventually loses the capacities distinctive of personhood nevertheless survives as the same functioning biological organism or human animal.

Whichever kind of view provides the most plausible account of metaphysical or numerical identity, it is not numerical identity that is at stake when a person who has undergone some kind of direct brain intervention says that they no longer recognize themselves or that they feel alienated in some way from the person they have become – nor when a patient states that they finally (or once again) feel like "themselves." These people do not seem to be saying that they have become metaphysically distinct entities. Rather, what they seem to be saying is that aspects of their characters, interests, values, emotional responses, embodiment, or relationships with others have changed – sometimes in ways they do not like or identify with, sometimes in ways that they do. The concepts of practical and narrative identity provide accounts of the kind of identity that seems to be at stake in such statements.

Practical Identity

The concept of practical identity shifts the focus of concerns about identity from metaphysical to practical and evaluative questions. Rather than addressing questions concerning what a human person essentially is, or the necessary and sufficient conditions for reidentifying an individual as the same over time, theories of practical identity seek to address questions concerning "who" we are as persons, that is, what distinctively characterizes each of our individual first-person perspectives. Françoise Baylis provides the following list of such questions: "Who am I? Where am I from? Where have I been? Where am I going? What do I care about? What do I stand for? Who do I want to be? Who am I becoming?" (2012, p. 117).

Christine Korsgaard understands practical identity as a normative self-conception, "a description under which you value yourself, under which you find your life to be worth living and your activities to be worth undertaking" (1996, p. 101). In Korsgaard's view, our practical identities are both discovered and constructed. On the one hand, our normative self-conceptions are shaped by all sorts of factors which we did not choose and over which we have limited control. These include our gender, sexual, racial, cultural, linguistic, or ethnic identity; our bodily and intellectual capacities; our family relationships; and the social, historical, and political contexts in which we live our lives, all of which define who we are and what matters to us. On the other hand, insofar as we are agents, our identities are not simply given. Rather, we actively construct or constitute our identities through authorial processes of reflection, deliberation, and decision. By reflecting on and deliberating about who we are, what we value, and how we should act, we ask ourselves whether our identities, and the beliefs, values, motives, and emotions arising from them, should be normative for us, that is, whether they constitute sufficient *reasons* for action. If the answer is no, then we may seek to revise or change them. Practical identity is therefore both a condition for and a product of our agency.

The concept of practical identity provides a way of explaining a person's actions third-personally and also justifying them first-personally. For example, we can explain why a teacher dedicates so much of her time to class preparation by understanding that the role of being a teacher importantly informs her practical identity; or why a man makes considerable efforts to visit and keep in contact with his grandchildren who live interstate by understanding that being a grandfather is central to his practical identity. Third-personally, these identifications are explanatory. But first-personally, for the teacher or the grandfather, these reasons may be both explanatory and justificatory. That our reasons for action are expressive of our practical identities is why they are normative for us and so guide our actions.

The notion of practical identity can therefore explain why the wife of the man with Parkinson's disease who has dedicated herself to caring for her husband feels so disoriented by his renewed confidence, energy, and independence following DBS and wishes that he were "nice and docile" again – because she seems to have lost her value as a caregiver and so no longer seems to have a justification for her actions. It can also explain why the ADHD sufferer does not like the indifferent, cynical person he judges himself to have become as a result of treatment. These changes seem like threats to his practical identity because he does not value being the kind of person whose actions are guided by these attitudes.

Korsgaard's emphasis on the first-person perspective and the role of agency in constituting our practical identities is important. One problem with her account of practical identity, however, is that her analysis of self-constitution is primarily synchronic; that is, it focuses on moments of deliberation and decision but not on the constitution of our identities over time. Another problem is that her analysis of the connection between our practical identities and normative commitments is overly strong, suggesting that "to violate [these commitments] is to lose your integrity and so your identity, and to no longer be who you are" (1996, p. 102). Although some commitments might be strongly identity constituting in this sense,

these remarks suggest that Korsgaard conceives of our practical identities as somewhat rigid and static. This interpretation of the concept of practical identity is thus not well suited to understanding personal change over time and might seem to lend support to problematic notions of authenticity as being true to one's "real" inner self, as we discuss below in section "The Ethics of Authenticity: A Relational Critique."

Narrative Identity

In the recent neuroethics literature, the concept of narrative identity has become increasingly influential, including as a way of explaining the sense of identity that is at stake in the perceived threats to personal identity posed by direct brain interventions (see, e.g., Glannon 2008; Bublitz and Merkel 2009; Schermer 2009, 2011; Schechtman 2010; Baylis 2011; Johansson et al. 2011; Witt et al. 2011; Walker 2012). The concept of narrative identity, like the concept of practical identity, is responsive to first-personal questions concerning "who" we are as persons (Ricoeur 1992), or what Schechtman (1996) refers to as questions of characterization. However, whereas Korsgaard's notion of practical identity is primarily synchronic, narrative accounts of personal identity seek to explain the diachronic constitution and reconstitution of identity. They are thus better able to explain how we construct our identities in response to the flux, fragmentation, and contingency that are inherent in living a human life over time.

Narratives are holistic, organizing, interpretive structures. Good stories, for example, integrate the different events they recount into intelligible temporal sequences, enabling us to understand what happened, when, to whom, and why. A good literary narrative does more than this. It enables the reader to make sense of the actions and motives of the characters, their inner lives, and their relations to one another, by situating their discrete actions, motives, desires, and beliefs within the broader explanatory context of the narrative whole. According to narrative identity theorists, such as Schechtman (1996), we constitute our personal identities by developing self-narratives that function in similar ways as literary narratives. Self-narratives are implicit organizing and integrating structures that provide a lens through which, as persons, we interpret our personal histories, past actions, and experiences; project ourselves into our futures by shaping our intentions and plans; and understand our character traits, habits, and emotional dispositions. Because self-narratives are selective and interpretive, they enable us to make psychological and evaluative sense of our selves, forging patterns of coherence and psychological intelligibility in response to the changing and fragmentary nature of our lived experience.

The claim that persons constitute their identities through the construction of self-narratives may seem implausible for several reasons. First, unlike literary narratives, with carefully structured, teleological plots, human lives are subject to randomness and contingency and unfold and change in haphazard and unpredictable ways. The concept of a self-narrative therefore seems to suggest

that, as persons, we have much more authorial control over our lives and identities than we in fact do (see, e.g., Christman 2004 for a version of this criticism). Second, the notion of authorship seems to imply that rather than living our lives, we must be constantly self-consciously reflecting on them and, moreover, trying to fit them into the form of a recognizable literary genre (see, e.g., Strawson 2004 for a version of this and the following criticism). Third, a narrative involves interpretation rather than bare representation of our personal histories, raising the question of how narrative theories can distinguish between self-narratives that are truthful and those that are confabulated, self-deceptive, or paranoid (Kennett and Matthews 2012). Responding to these concerns will help to clarify further the notion of narrative identity and its relevance for neuroethics.

In response to the first and second worries, it is important to emphasize that the concept of narrative identity does not imply either that human lives must have the tight structure of a plot, or that rather than living we should be constantly self-reflecting. The point is rather that, in the words of Charles Taylor, persons are “self-interpreting animals” (Taylor 1985, p. 45); that is, self-interpretation is integral to the activity of living a human life. Further, our self-interpreting activities deploy capacities for narrative understanding – for identifying and constructing patterns of coherence and meaning. Although narrative self-interpretations need not take the form of tightly structured or articulate literary narratives or even stories, as Schechtman (1996, p. 114) argues, they should be articulable to some degree, for example, in response to others’ requests for explanation of a person’s actions, motives, or emotional responses. The concern that narrative identity is inconsistent with acknowledging the extent to which human lives are subject to randomness and contingency is, therefore, misplaced. Narrative understanding is a way of making sense of flux, contingency, and temporal change. Contingency – illness, accident, trauma, and bereavement – can derail even the most carefully planned life and challenge our self-narratives. To reconstruct our lives and reconstitute our identities in the face of such contingency, we need to find ways of incorporating it into our self-understandings and life stories. Thus narrative coherence is dynamic and provisional. The patterns of coherence within a person’s identity shift and change over time, in response to contingency, or changes to a person’s commitments and values, intimate relationships, or sociopolitical environment.

In response to the third worry, although self-narratives are dynamic and provisional, it is not the case that any old story a person tells about him or her self can count as a self-constituting narrative. Narrative identity theorists have proposed a number of different constraints on self-constituting narratives. Schechtman proposes that a self-constituting narrative must meet the “reality” constraint, which specifies that a person’s self-narrative must cohere with reality; it cannot be delusional, psychotic, based on gross factual errors, resistant to revision in light of contrary evidence, or inconsistent with others’ views about oneself (Schechtman 1996, pp. 119–128). Hilde Lindemann Nelson (2001) proposes that to be self-constituting, a self-narrative must be “credible,” meaning that it must have strong explanatory force, fit the evidence, and correlate with a person’s actions. On either of these views, confabulatory self-narratives are not identity constituting.

The notion of narrative identity can clarify, in a similar way to the notion of practical identity, the sense in which neurotechnologies that radically alter a person's mood, cognitive capacities, or behavior might be seen from a first- or third-person perspective as potential threats to identity. But because of its focus on self-constitution over time, and capacity to articulate the dynamic nature of identity, narrative identity provides a better theoretical framework for understanding the ethical issues raised by such identity changes. As Schechtman (2010) explains in discussing the use of DBS to treat Parkinson's disease, psychological changes that are brought about suddenly and in ways that seem to be beyond the authorial control of the patient can cause significant disruptions to their self-narrative, making it difficult to construct a coherent narrative that connects their present experiences and sense of self to their past: "In general, patients who report adjustment problems seem to have a hard time seeing the life they were leading after treatment as the continuation of the life they were leading before, and so find themselves having to reinvent themselves" (2010, p. 138). Because narrative identity is dynamic, however, the notion of narrative identity can also help to explain how such self-reinvention is possible. That is, if the patient, along with his or her close associates, can construct an integrated narrative that makes sense of radical psychological change within the broader context of the person's life and that connects this change with the person's plans, goals, and relationships – for example, the goal of battling illness: "A longer term narrative perspective will thus provide a viewpoint from which what might look like a narrative break, up close, can be seen as a small segment of a continuous and self-expressive life narrative" (2010, p. 138).

Some disruptions brought about by neurotechnological interventions are of course so profound that the kind of reinvention Schechtman discusses is not possible. Walter Glannon discusses the case of a patient for whom treatment by DBS, while it controlled the motor symptoms of Parkinson's disease, resulted in mania, leaving the patient with the devastating choice between being admitted to a nursing home because of serious physical disability despite intact cognitive and affective capacities or being admitted to a psychiatric ward because of his mania (2008, p. 290). In relation to this case, Glannon raises the following questions: "How much disruption can one's life narrative accommodate without threatening the integrity of the whole? Is there a threshold below which alteration of the psyche is substantial enough to alter the identity of the person?" (2008, p. 291). In this kind of case, narrative reinvention of the self may not be possible, but as Baylis suggests, this is not so much because the person's identity has been radically disrupted. Rather, it is because the patient "is no longer able to contribute meaningfully to the authoring of [his] life" because both the illness and the treatment have impaired his capacities for agency (2011).

The following section provides an argument in support of this claim by explicating the relationships between identity, agency, and autonomy. In so doing it also investigates the adequacy of an ethics of authenticity for assessing the ethical implications of changes in identity arising from the use of neurotechnologies.

The Ethics of Authenticity: A Relational Critique

The ethics of authenticity might seem to provide a compelling language for articulating the issues raised by the effects of DBS or psychopharmaceuticals on personal identity. One reason for this is that the ideal of authenticity as being "true to oneself" seems to resonate with both first- and third-person descriptions. As some of the empirical studies cited above show, patients often characterize these effects in terms of feeling either unlike themselves or alienated from their characteristics, or, alternatively, as feeling like themselves once again, or even as becoming who they really are for the first time. Another reason is that, as Elliot points out, the notion of authenticity as a normative ideal has a strong moral pull in our culture (2003, p. 34). The idea that one should strive to be oneself, to get in touch with one's "inner depths" or listen to one's "inner voice," seems to play a central role in our conception of what is involved in leading a good, meaningful, and fulfilling human life: "The ethic of authenticity tells us that meaning is not to be found by looking outside ourselves, but by looking inward. The meaningful life is an authentic life, and authenticity can be discovered only through an inner journey" (2003, p. 35; see also 2011, p. 369). As a corollary, we judge those who are inauthentic – who follow the crowd, or are overly conformist – as in some sense morally compromised or as leading lives that are less than satisfactory. The authentic life is thus culturally valued as a better life.

But what does "being true to oneself" mean? As Elliot's analysis makes clear, the ideal of authenticity involves many different, and sometimes conflicting, strands: not being a fake; looking inward rather than outward to discover one's true or core self; leading a fulfilled and meaningful life; reconciling the inner self with one's outward presentation; and also being flexible and engaging in activities of self-transformation. Insofar as Elliot's aim is cultural diagnosis and critique, his analysis of the somewhat protean shape of the ideal of authenticity is not problematic. The notion of authenticity becomes more problematic, however, when it is used (including by Elliot himself) to frame philosophical debates about neurotechnological treatment and enhancement. As Levy argues (2011), these debates have coalesced around two conflicting strands of the notion of authenticity: self-discovery, and self-creation or self-transformation (see also Bublitz and Merkel 2009 for a related categorization). Levy characterizes these as stemming from "rival outlooks on what it means to be human" (2011, p. 314) and argues that both outlooks are deeply culturally entrenched in our attitudes toward identity. The argument of this section of the chapter is twofold: that both conceptions of authenticity are problematic and premised on individualistic assumptions; and that a relational and narrative understanding of identity and autonomy can integrate the plausible aspects of each conception, while eschewing individualism.

The notion of authenticity as self-discovery admits of more and less plausible interpretations. In its less plausible variants, authenticity or being true to oneself is taken to mean discovering – and expressing in one's actions and behavior – one's essential nature, personality, or defining core characteristics. The self, on this view,

is understood as a static inner entity, a true or essential self, awaiting discovery. The process of discovery is variously interpreted as looking deep into oneself in solitary introspection, finding one's inner voice, and remaking one's life, character, or body to make them correctly express this "true self." In enhancement discourses, this can involve altering one's "mutable self-presentation to match the enduring inner self," stripping away and "remolding the outer body in conformity with the inner being" (Elliot 2003, pp. 20–21, 32). Elliot discusses as examples of this conception of self-discovery some of the discourses surrounding male to female sex reassignment surgery, body building, and breast reduction or augmentation surgery, which often represent body modification as a quest to become the true self one always was. Similarly, psychopharmaceuticals may be used in pursuing the attainment of a "true self" in psychological or emotional terms (Kraemer 2011a, p. 52; see also DeGrazia 2005, p. 208). Elliot himself does not seem to endorse the notion of an essential self awaiting discovery, but he does seem to endorse the idea that people have "true selves" or "relatively stable and coherent set(s) of mental and physical attributes" (2003, p. 50). Another theorist who seems to appeal to the notion of the true self in the context of debates about neurotechnological intervention is Kraemer (2011a, b). In her analysis of Schupbach and colleagues' (2006) study of DBS patients, Kraemer (2011b) argues that the ethical issues at stake in identity changes resulting from DBS can best be understood in terms of an ethics of authenticity, and seems to interpret authenticity in terms of a true, real, or ideal self.

In our view, the notion of a true, inner, essential self is implausible, not only because it fails to account for the dynamic, embodied, and narrative constitution of identity but also because it fails to account for the relational dimensions of identity – assuming that the true self is a deep, inherent self, intrinsic to the person, which would remain the same regardless of the person's embodiment, or their social, cultural, and historical situation. What discourses of self-discovery might, more plausibly, be attempting to capture, as Levy points out, is the recognition "that people *do* have dispositions and talents and personalities, which fit them better for some activities than for others, and which make some ways of life more fulfilling for them than others" (2011, p. 312). Such discourses might also be attempting to capture the extent to which our identities are shaped by biological, social, historical, and cultural factors over which, as agents, we exercise little or only limited control – such as our sexed embodiment; who our parents are; our linguistic, historical and cultural heritage; our susceptibility to genetically inherited diseases; and so on. We suggest below, however, that this more plausible reading of the notion of self-discovery is better understood in terms of a relational account of narrative identity.

The notion of authenticity as self-creation also admits of more and less plausible interpretations. The least plausible interpretation is a caricatured version of the existentialist notions of radical choice and radical freedom. DeGrazia (2000) and Levy (2011), for example, interpret Sartre as committed to the view that every choice we make involves a radical act of self-creation: "The authentic individual recognizes that literally *nothing* – not their genes, not their past history, not their social relationships or their talents and skills, not morality and not God – stands in the way of their self-creation" (Levy 2011, p. 311). The most plausible

interpretation, and the one that is most influential in neuroethics, is that of DeGrazia, who criticizes Elliot's conception of authenticity as based on a "misleading image of the self as 'given', static, something there to be discovered," arguing in contrast: "One can be true to oneself even as one deliberately transforms and to some extent creates oneself" (2000, p. 35).

DeGrazia's account of authenticity as self-creation draws on a narrative notion of identity and links self-creation to autonomy. He understands self-creation as "the conscious, deliberate shaping of one's own personality, character, other significant traits. . .or life direction" (2005, pp. 89–90). In his view, projects of self-creation arise from narrative identity or a person's sense of self. However, whereas a person need not take an active, self-directing role in shaping his or her self-narrative, the process of self-creation

> occurs when an individual takes an active role in authoring the biography, making it a *lived* biography. Rather than wondering about how later chapters will turn out, or wondering how they'll turn out but with no sense of controlling their direction, the self-creator endeavors to write those later chapters – and perhaps, in light of the evolving story, edit earlier chapters as different themes emerge as critical and self-discoveries put old details in a different light (2005, p. 107).

The conception of narrative identity implied by this quotation seems odd. On the one hand, DeGrazia characterizes narrative identity as a person's first-person interpretive "inner story" through which she comes to know and understand herself. He also regards having a self-narrative as a precondition for prudential planning and moral agency (2005, p. 89). On the other hand, in this quotation the agential dimensions of narrative identity are obscured, and the implication seems to be that a person's self-narrative could simply unfold without her actively authoring that narrative. Active authorship, DeGrazia seems to be suggesting, is characteristic of self-creation rather than narrative identity.

So what does self-creating authorship involve? DeGrazia acknowledges that self-creation does not require or imply "unlimited capacity for self-change and control over one's destiny" (2005, p. 91) and that projects of self-change are constrained by the inevitable dependencies and finitude of human life and shaped by a person's genetic makeup and embodiment, and by randomness and contingency. Thus "while self-creation is possible, the range of possibilities available to a person is both opened up and limited by other major factors and processes that shape our lives" (2005, p. 92). So how, according to DeGrazia, do we take an active role in authoring our biographies, thereby engaging in projects of self-creation? His answer is by making plans and setting goals about the kind of person we want to be or the kind of life we want to live and then acting to realize those plans and goals through our choices and actions. Not all projects of self-creation are authentic, however. A person may have set himself the goal of being a lawyer and may have worked hard for many years at university and in his first professional job in a corporate law firm, but then come to realize that the kind of life he is leading is not really "him" and that he does not identify with the goal that seems to have been motivating his choices and actions. He realizes that he has been somewhat self-deceived in the pursuit of this goal, seeking to satisfy other people's

expectations without adequately reflecting on whether it is really what he wants to do with his life. To be authentic, according to DeGrazia, a project of self-creation must be autonomous and honest (2005, p. 112): it must be expressive of the person's own preferences and values, and he must identify with it on the basis of careful reflection (2005, p. 102).

In contrast to Elliot, who worries about whether changes to a person's identity brought about by neurotechnologies compromise authenticity, DeGrazia argues that such changes count as authentic so long as they express the person's values and he or she reflectively identifies with these changes. He gives the example of Marina, a woman with a troubled family background and a history of failed relationships. Through hard work and perseverance, Marina has managed to achieve success in her career, but she is not satisfied with aspects of her character, in particular her tendency to be pensive and brooding. What she wants to be is a person who is "more outgoing, confident, and decisive professionally; less prone to feelings of being socially excluded, slighted, or unworthy of a good partner; and less obsessional generally" (2000, p. 35). Having briefly tried to effect these changes through psychotherapy, she asks her psychiatrist for a prescription for Prozac, which she thinks may bring about the desired result more cheaply and efficiently. DeGrazia argues that whether Marina uses psychotherapy or psychopharmaceuticals to effect the desired change is irrelevant in determining whether it is authentic or inauthentic. What matters is whether it is in line with her values and self-conception and whether she identifies with the person she is seeking to become posttreatment.

The concern of this chapter is not to address the question of whether identity changes brought about by enhancement, such as in the case of Marina, can be authentic. It is rather to assess the adequacy of the notion of authenticity for understanding the ethical implications of identity changes arising from neurotechnological interventions. In our view the self-creation interpretation of authenticity is more plausible than the notion of self-discovery, insofar as it is consistent with a dynamic and narrative account of identity, and emphasizes the agential, authorial dimensions of identity construction. However, the notion of self-creation is misleading for two reasons. First, it is premised on an overly individualistic conception of identity. Second, as DeGrazia acknowledges, the ethically relevant consideration is whether identity changes brought about by neurotechnological interventions are autonomous. The appeal to authenticity is redundant and blurs the distinction between narrative identity and autonomy.

DeGrazia appears to conceive of narrative identity primarily as a matter of self-ascription. In discussing the example of Marina, he says "it is ultimately up to Marina to determine what counts as Marina and what counts as not-Marina" and "if Marina is able to rid herself of traits with which she does not identify, and decides that the 'real Marina' does not have those traits, no one is in a position to correct her" (2000, pp. 37, 38). In a later discussion (2005, pp. 86–88), he acknowledges that others do in fact play a role in the constitution of narrative identity, in three main ways. First, some interpersonal relationships are central to our identities, and so those particular others play "starring roles" in one's self-narrative. Second, when others "mirror" or reflect back to us their images or conceptions of who we are, this

mirroring can consolidate (or distort) our self-narratives. Third, others play an important epistemic role in providing a reality check on our self-narratives, helping to identify self-narratives that are deluded or inaccurate. With respect to this third role, however, DeGrazia insists that, except in cases where our self-narratives do not meet Schechtman's reality constraint, our first-person self-narratives must always be regarded as more authoritative.

DeGrazia's account of the role of others in the construction of our self-narratives is, however, insufficiently relational and still adheres to a view of the self as an inner citadel, to which others may be admitted but only on one's own terms. It is true that others do play the three roles identified by DeGrazia. However, we endorse a more thoroughly relational view of identity, according to which our self-narratives are not discrete and self-contained inner stories. Rather, our self-narratives are constructed through interpersonal relationships and in the context of the larger social, historical, political, and cultural narratives within which we live our lives and seek to define and understand ourselves. As Mackenzie has argued elsewhere, "We are always already caught up in relations with others, even prior to birth, and we acquire identities and agency within a community of agents and are constrained by complex networks of social norms, institutions, practices, conventions, expectations and attitudes" (2008a).

This view integrates insights from feminist relational theory with the concept of narrative identity. According to feminist relational theory, self-identity is intersubjectively and socially constituted, in relations of dependence and interdependence, beginning with the infant's dependency on and earliest interactions with her caregivers. Annette Baier coins the term "second persons" to characterize the implications of this primary intersubjectivity; namely, that persons are "essentially successors, heirs to other persons who formed and cared for them" (Baier 1985, p. 85). This primary intersubjectivity, which is rooted in corporeal interactions with caregivers, is subsequently layered by more complex forms of intersubjectivity, which are made possible by cognitive and linguistic development, and by our participation in the social world. This complex intersubjective layering includes the way our identities are shaped by familial and personal relationships; by our embodiment; by social identity categories, such as those relating to gender, race, ethnicity, class, sexual orientation, and disability; and by the cultural, religious, political, and geographical communities into which we were born or to which we now belong. According to feminist relational theory, this intersubjective shaping of our identities can be enabling or damaging – although often it will be a mixture of both. It is enabling to the extent that it fosters a person's capacities to fashion an autonomous self-narrative; it is damaging if interpersonal relationships and social structures oppressively constrain the range of identity-constituting narratives a person can enact, or thwart the development and exercise of autonomy competence.

Feminist relational theorists hold that autonomy is a competence, involving a complex repertoire or suite of reflective skills, which may be developed and exercised to varying degrees and in different domains (Meyers 1989). Autonomy competence encompasses not just the minimal requirements of legal competence – understanding, minimal rationality, and the capacity to communicate one's

decision – but an array of complex competences. These include volitional skills, such as self-control and motivational decisiveness; emotional skills, such as the capacity to interpret and regulate one's own emotions; imaginative skills, required for understanding the implications of one's decisions and envisaging alternative possible courses of action; and capacities to reflect critically on social norms and values (Meyers 1989; Mackenzie 2000, 2002). Most importantly, relational theorists also hold that these autonomy skills emerge developmentally and are sustained and exercised in the context of significant social relationships. Hence, autonomy competence is a relationally or socially constituted capacity, which requires sustained interpersonal, social, and institutional scaffolding.

Because autonomy competence is relationally constituted, its development and exercise can be impaired by abusive, coercive, or disrespectful personal relationships and by oppressive social structures involving social relations of domination, exclusion, or marginalization (Mackenzie and Stoljar 2000; Friedman 2003; Oshana 2006). Social oppression can also impair autonomy by restricting the range of identity-constituting narratives available to members of oppressed social groups, either overtly or via oppressive stereotypes (Nelson 2001; Baylis 2012), and by refusals of uptake or social recognition (Anderson and Honneth 2005). Relational autonomy theorists claim that the internalization of oppressive social stereotypes, and social relations of misrecognition that deny members of oppressed social groups the *status* of being autonomous agents, can further impair autonomy by undermining a person's sense of him or her self as an autonomous agent. One way this can occur is by corroding self-evaluative attitudes of self-respect (regarding oneself as the moral equal of others), self-trust (the capacity to trust one's own convictions, emotional responses, and judgments), and self-esteem or self-worth (thinking of oneself, one's life, and one's undertakings as meaningful and worthwhile) (McLeod 2002; Anderson and Honneth 2005; Mackenzie 2008b).

The implication of feminist relational theory for narrative identity is that we cannot be self-creators but "are (and can only be) dynamic complex co-creations informed by the perspectives and creative intentions of others" (Baylis 2012, p. 118). This is because "one's first-personal perspective is always already an intersubjective, intercorporeal perspective situated in a material and cultural world" (Atkins 2008, p. 56). Constructing a narrative identity is therefore an ongoing negotiation between first-person self-ascriptions of identity, second-person recognition (or misrecognition) by others, and third-person identity ascriptions, such as ascriptions of personality, character, action attributions, and so on.

This relational negotiation of identity is evident in the case described by Schupbach and colleagues (2006) of the DBS patient, who claimed to feel more like himself following treatment but whose wife had a very different view of his identity change. This case raises the question, addressed by DeGrazia, of what weight and authority should be given to the person's self-ascriptions versus third-person ascriptions. In response to this case, Kraemer (2011b), appealing to the ethics of authenticity, seems to agree with DeGrazia that first-person ascriptions are always more authoritative. She characterizes this case as one in which the patient feels authentic because he has recovered his autonomy, which Kraemer interprets as

being "master of his own destiny," that is, being able to live his own life rather than "existing as someone else's heteronomous object of care" (2011b).

In contrast Baylis, who endorses a thoroughly relational conception of narrative identity, offers a more nuanced analysis of cases like this (although she does not discuss this specific case) (2011, 2012). Baylis proposes what she refers to as an equilibrium constraint on identity-constituting self-narratives: a balance between a person's first-person self-ascriptions and others' perceptions. On this view, a self-narrative is identity constituting if it achieves a "temporary (even if very fragile) stability" (2012, p. 123) between first-, second-, and third-person perspectives. Achieving this stability is an ongoing "interpersonal, communicative activity" (2012, p. 123). Baylis suggests that when people's identity claims are challenged by others, they have several options including the following: to try to project their self-narratives more successfully, to revise their projected self-narratives in response to others' reactions, to defer to others' perceptions, to reject others' interpretations of their character or actions, or to seek recognition of their identities within different communities of belonging. Self-interpretation thus involves "an iterative cycle of 'self'-perception, 'self-projection, 'other'-perception, and 'other'-reaction" (2012, p. 128).

In the case described by Schupbach and colleagues (2006), the patient seems both to reject his wife's interpretation of who he is and to want to seek out a different community of belonging in which he will be recognized for who he takes himself to be. This is what Baylis refers to as his "preferred self-narrative" (2011). But whether he will be able to enact or "perform" this self-narrative and achieve a temporary stability will not be entirely up to him, since it will be subject not only to uptake by others but also to the progress of the disease and the success of DBS in treating it. This is why achieving equilibrium requires finding a balance between how the patient perceives and understands himself, how others see and understand him, and the constraints of his lived embodiment (2011). In social contexts in which the beliefs and attitudes of others toward physical and psychological disability are stigmatizing and negative, achieving equilibrium will be a fraught and difficult process (with or without neurotechnological intervention), often resulting in feelings of self-alienation. Baylis argues, however, that this sense of self-alienation should not be understood as the result of a threat to identity caused by disability or neurotechnological intervention. Baylis does not deny that life-changing disruptions to a person's narrative identity "undeniably constrain[s] the dialectical process of identity formation (and thereby alters a planned or anticipated narrative)" (2011). However, in her view, such experiences of self-alienation are usually either the result of the internalization of social stereotypes and social relations of misrecognition or the effect of direct brain interventions that impair a person's capacities for autonomous agency (2011).

Baylis' equilibrium constraint and her analysis of the likely reasons for the experiences of self-alienation that are sometimes described in patient narratives seem plausible in our view. Combining Baylis' analysis with the relational analysis of autonomy sketched out above, it should now be clear why the ethics of authenticity blurs the distinction between narrative identity and autonomy. The salient

issue, as DeGrazia's notion of authenticity as self-creation implicitly acknowledges, is not whether such interventions threaten identity, but whether they impair autonomy competence. However, by framing debates about neurotechnological interventions in terms of potential threats to or enhancements of identity, the ethics of authenticity obscures this question. Once this question is brought to the fore, however, it is evident that it can only be answered case by case. In some cases, such as in the tragic case discussed by Glannon and mentioned at the end of the preceding section, an intervention such as DBS can disrupt a person's autonomy competence to such an extent that he is unable to engage in narrative self-revision. In other cases, neurotechnological interventions, by alleviating the physical or psychological effects of illness (including mental illness), may thereby restore some of the volitional, emotional, motivational, imaginative, and critically reflective capacities necessary for autonomous deliberation and action. In so doing, such interventions may make it possible for a person to reengage in the process of reconstructing or repairing an integrated narrative identity. Relational theory shows, however, that a person's ability to do so is not just up to the person him or herself; it is also a matter of the extent to which others enable him/her to do so, by providing the social scaffolding and recognition required for autonomous self-narration.

Conclusion

This chapter has shown that in order to understand what might be at stake in phenomenological descriptions of disorienting, or liberating, change consequent upon various neurotechnological interventions, it is important to clarify and distinguish the concepts of identity, authenticity, and autonomy. The first section distinguished three different concepts of personal identity – numerical, practical, and narrative – and argued that the concept of narrative identity enables us to make best sense of these first-person descriptions. The second section showed why the ethics of authenticity provides a misleading normative framework for understanding the ethical issues at stake in neurotechnological interventions. First, the notion of authenticity, as it has been understood in neuroethical debates, is ambiguous between self-discovery and self-creation. Second, the notion of self-discovery is implausible. The notion of self-creation is more plausible insofar as it draws on a dynamic, narrative conception of identity. However, it blurs the distinction between identity and autonomy and so obscures the central ethical issue it seeks to address. Third, both interpretations of authenticity fail to account for the relational dynamics of identity and autonomy. We proposed that a relational and narrative account of identity and autonomy can incorporate the most plausible aspects of the ethics of authenticity and can explain what is at stake in first-person phenomenological descriptions of self-alienation. Such descriptions, as Baylis argues, draw attention to the distress experienced as a result of being unable to achieve equilibrium in one's self-narrative. This distress, in our view, points to threats to autonomy rather than to identity or authenticity, as the salient concern underlying narratives of self-alienation.

Dissociative Identity Disorder and Narrative

Abstract

Dissociative identity disorder (DID) has been a subject of fascination to clinicians, philosophers, and the general public for well over a century. There are many reasons for this, not the least of which is the way in which this disorder challenges ordinary understandings of personal identity. It is not easy to say how many people are present in an encounter with a DID patient. Since facts about personal identity are intimately connected to prudential reasoning and the assignment of moral responsibility, perplexity about identity in these cases has potentially important practical implications. This chapter offers a theoretical framework for the fruitful investigation of questions of personal identity in DID in the form of the Narrative Self-Constitution View which argues that individuals constitute themselves as persons by developing and operating with an implicit autobiographical narrative in which they apply the normative constraints of personhood to their own lives. View does not deliver a definitive answer to the question of how many persons one is confronted with in encountering a DID patient, but it does provide important insights into why a definitive answer should not be expected and sheds light on the role of embodiment in personal identity. The further value of this approach is demonstrated by showing how it can illuminate questions of moral and criminal responsibility in DID.

Introduction

Dissociative identity disorder (DID), formerly multiple personality disorder (MPD), has been a subject of fascination to clinicians, philosophers, and the general public for well over a century. There are many reasons for this, not the least of which is the way in which this disorder challenges ordinary understandings of *personal identity*. It is not easy to say how many people are present in an encounter with a DID patient. Since facts about personal identity are intimately connected to prudential reasoning and the assignment of moral responsibility, perplexity about identity in these cases has potentially important practical implications.

This chapter focuses on issues of personal identity in DID, offering a theoretical framework for exploring these questions in the form of a narrative account of personhood. The first step is to get a slightly more developed picture of the phenomenon of DID and of some of the outstanding disputes about the nature of the disorder. Next a *narrative* account of personal identity – the Narrative Self-Constitution View– will be introduced and applied to the case of DID. The Narrative Self-Constitution View does not provide a straightforward answer to the question of how many persons are present in an encounter with a DID patient, but it does offer important insight into this complex disorder, showing why a straightforward answer is not to be expected. The usefulness of this insight will be demonstrated by looking at the way in which the Narrative Self-Constitution View can illuminate tricky questions about moral and criminal responsibility that arise in cases of DID.

Some Preliminaries

According to the DSM-IV DID is characterized, among other diagnostic criteria, by "two or more distinct identities or personality states," at least two of which "recurrently take control of the person's behavior." Patients also demonstrate an "inability to recall important personal information that is too extensive to be explained by ordinary forgetfulness," and experience frequent blackouts. Slight modifications of these criteria have been proposed for DSM-V, but these will not be important for present purposes.

A general picture of what DID is like is familiar from popular depictions such as those found in *Sybil* and *The Three Faces of Eve*. The differences between

personality states in DID can be quite profound. The distinct identities or "alters" may be vastly disparate in temperament, values, and commitments. Usually, there are amnesiac barriers running in at least one direction, so that one alter lacks memory of what another has said or done, resulting in the blackouts, forgetfulness, and lost time that characterize the disorder (Dorahy 2001). Frequently there is a "host" personality that represents the core presentation which is interrupted by alters. The alters may live quite different lives, engaging in different activities and interacting with different groups of people. They may claim to be distinct individuals and may describe themselves as being different ages or sexes from one another and from the human body through which they are expressed. There are also reports of alters differing from one another in various physiological characteristics. It is claimed, for instance, that alters may have optical differences (one needing corrective lenses where another does not), or different allergic responses, or handedness. Some research has found that alters also differ in EEG and other patterns of brain activity (Coons 1988; Reinders et al. 2006).

The question of just how deep the differences between alters run is a contested one, however, and there has been a fair bit of work aimed at showing that the divisions among distinct personalities in DID are not as sharp as they are often taken to be. Studies have shown that although there are amnesiac barriers between alters, there is more leakage than there is typically thought to be. In particular, if we concentrate on types of memory other than autobiographical (the learning of skills, for instance) or on priming effects, there seems to be a good deal of carryover between alters, suggesting that the psyches of the individual personalities are not as hermetically sealed as it might at first seem (Eich et al. 1997). There have also been charges that claims of physiological differences among alters are exaggerated and anecdotal (Merckelbach et al. 2002).

Another aspect of the disorder that is a matter of deep controversy is its etiology. *DID* is widely believed to be a posttraumatic developmental pathology. A standard theory is that dissociation occurs as a protective response to childhood abuse or trauma. Alters develop when a traumatized child repeatedly compartmentalizes overwhelming emotions and memories, ultimately resulting in distinct personalities designed to deal with these powerful feelings (e.g., Loewenstein and Putnam 1990). This account enjoyed a great deal of popular attention during the 1990s with several dramatic and well-publicized stories involving "recovered memories" of childhood sexual abuse. In these cases, flashback memories of abuse or other trauma resurfaced in adulthood. Such memories were often associated with a clinical presentation of DID and often occurred during hypnosis or in the course of other therapeutic interventions. There has, however, been a strong challenge posed to the idea of recovered memory in general and to the etiology of DID in childhood trauma in particular. The "memories" recovered, it is argued, are the result of hypnotic, therapeutic, or cultural suggestions on a vulnerable mind. While claims of remembered trauma may be quite sincere, opponents argue, they are nevertheless unreliable. This has led some detractors from the standard view to question the very phenomenon of DID as a discrete syndrome (Loftus 1993; Piper and Merskey 2004).

Questions about the actual distinctness of the alters have a clear potential to impact the assessment of how many persons are present in a DID patient, and although somewhat more remotely connected, questions of etiology may also enter into these judgments. Conclusions drawn while these issues remain in question must therefore be considered provisional, but it is possible nevertheless to make quite a bit of progress in understanding how judgments of personal identity can be made in the face of this perplexing disorder. The next section introduces an account of personhood and personal identity that will contribute to such progress.

The Narrative Approach

There are, of course, many different theoretical accounts of *personhood* and *personal identity*, most of which have direct implications for the question of how many persons are present in a case of DID. Views that define identity in *narrative* terms are especially illuminating in this context. There are a wide range of different views that fall under this general rubric, and they differ in important respects (Baylis 2012; Bruner 1990; Dennett 1992; Goldie 2012; Ricoeur 1992; Taylor 1989). What they all have in common is the claim that it is illuminating to think about persons and their identities in narrative terms. The version of this approach employed here will be the Narrative Self-Constitution View developed by Schechtman (1996, 2011). According to this view, persons constitute themselves by developing a largely implicit autobiographical narrative which serves as the lens through which they experience and act on the world. The idea is not a complicated one: basically as children mature, they learn to think about the events in their lives as connected to one another by a certain kind of logic involving both natural causes and human motivations. This way of thinking about oneself and one's life has both phenomenological and behavioral effects, and these effects constitute personhood.

Here is an example of the relevant phenomenon: take an event described neutrally as stepping off of an airplane at a particular airport. For the person leaving the plane, this event will be very different if she is (a) arriving at the country where she will finally pick up the child whose adoption she has eagerly anticipated, (b) arriving at the country of her deployment for dangerous military duty having left small children behind at home, (c) arriving at the place where she will give an academic address and receive a prestigious reward, or (d) arriving for the funeral of a beloved relative who died unexpectedly and very young. The same neutrally described event will yield a different experience and lead to different actions and decisions in each of these cases because it is part of a different narrative and it takes its character from the story of which it is a part.

The Narrative Self-Constitution View claims that all of our experiences are like this. As persons interact with the world, they carry with them an implicit awareness of the basic elements of their histories and anticipated trajectories which at each moment influences both their experience of the present and their deliberations about what to do next. According to this account, persons are able to have the kinds of experiences and engage in the kinds of behaviors they do precisely because they

bring their ongoing life stories to bear on the present and so structure their experience of the world according to an ongoing autobiographical *narrative*. The unity of a single person, according to this view, is the unity of a narrative, and the events that are included in a person's autobiographical narrative are, for that reason, events in *her* life.

This is, of course, only a sketch of a rather complicated position. A full development of the view is beyond the scope of this discussion, but to see its implications for questions of *personal identity* in DID, it will be necessary to have at hand a few more details about the view and the way in which it is motivated. The Narrative Self-Constitution View falls within a broad tradition that employs a particular understanding of what it means to be a person. This understanding defines *personhood* in terms of the kinds of capacities that are characteristic of typical adult humans and are, so far as we know, unique to human existence. These capacities get described differently by different theorists, but crucially they involve the extremely complex kinds of interactions persons are able to have with one another. In particular, there is emphasis on the fact that persons are beings who are subject to norms of thought and action – they can be legitimately criticized for being immoral or irrational in ways that other animals cannot.

The task those who work in this tradition set themselves is that of explaining what relation or relations must be used to define persons in order to capture this fundamental characteristic. It is against this backdrop that the Narrative Self-Constitution View is developed. The idea is that these kinds of judgments are possible because there is a very basic and general conception of what constitutes an intelligible human life that all persons share. There are of course variations of detail over time and among cultures and subcultures, and fine-tuned ideas of intelligibility are variable. There is, however, enough overlap to yield a robust conception of personhood defined in terms of what is held in common – the most basic conditions of intelligibility. The Narrative Self-Constitution View argues that in order to be an entity rightly held to the norms that define persons, one needs first to understand these basic norms and see them as a demand on one's own life. Someone becomes a being capable of moral *agency* or prudential reasoning, and so a being subject to the norms they imply, by understanding what it is to be a moral agent or prudential reasoner and understanding also that he is one. The cognitive and other skills required for *being* a person are the same as those required for *recognizing oneself* as a person among other people. The Narrative Self-Constitution View argues that the form this recognition takes is precisely the structuring of one's life according to an implicit autobiographical narrative which meets the constraints of intelligibility for the biography of a person. This involves both interpreting one's life in terms of these norms of intelligibility and also actively guiding one's life, so far as possible, to meet them.

This requirement implies that personal identity cannot be successfully constituted by just any self-understanding that is basically narrative in form. Someone cannot make any actions and experiences his, simply by telling himself a story in which they are his. Someone may, for instance, sincerely believe that he led the troops at Waterloo on June 18, 1815, but this does not make him Napoleon.

In order to effectively constitute a person, there are two constraints an autobiographical narrative must meet. The first is the "*articulation constraint*." Although the autobiographical *narrative* envisioned in the Narrative Self-Constitution View is mostly implicit, it is required that a person be able to articulate the narrative locally where appropriate. Roughly this means that in the face of a range of questions – e.g., How long have you been here? Where do you live? What do you do for a living? Why did you choose that car? Why did you yell at him like that; what he did seemed reasonable? – a person should have something to say. The answer may sometimes be along the lines of "I don't know, I'm drawing a blank right now," or "I don't know, I make it a point to express my emotions as I feel them and I just don't reflect any further," or even "None of your business." The requirement is not that a person's motives will always be transparent to her or that she must always produce them when asked but rather that she must recognize herself as subject to a certain explanatory burden, at least internally. An individual who does not know where she comes from or if she has a family or a job or why she did what she did *and* is completely unperturbed by this fact is, according to this view, lacking a key feature of personhood.

The second constraint an identity-constituting narrative must meet is the "*reality constraint*." It requires a narrative to conform to the basic contours of accepted facts, where this is understood in a common, everyday sense, and not in any strong metaphysical sense. A narrative that involves getting from Chicago to Paris in under 40 s, for instance, or changing sexes every other day, or being in two places at one time is ruled out. The individual with Napoleonic delusions described earlier would not meet this requirement because he could not give a coherent and realistic narrative that involves undertaking Napoleon's actions. The violation does not lie directly in the fact that he thinks he is Napoleon when he isn't (that would make the view circular), but rather in details, he would need to include in his narrative about what height he is, where he lives, what language he speaks, who he is married to, what year it is now, what year the exploits he is claiming as his own took place, and how long humans live. In order to coherently claim Napoleon's actions as his own, this individual would need to deny accepted matters of fact, thus violating the reality constraint.

In basic outline, then, the Narrative Self-Constitution View says that we constitute our identities as persons by generating and operating with an autobiographical narrative that meets the articulation and reality constraints. There is another way of phrasing the guiding idea behind these constraints that will be helpful in what follows. The Narrative Self-Constitution View holds that personhood requires not only that someone have a conception of herself as subject to the norms of personhood but that her first-personal autobiography must fundamentally cohere with the natural third-person view of her history. There will, of course, be disagreements on points of interpretation – someone may think she is gregarious and funny, while others think she is obnoxious, or she may think that she is full of integrity, while others think she is rationalizing her own bad behavior – because there is usually more than one intelligible way to interpret a history. Small mistakes of detail may also be made from either the first- or third-personal perspective, and these too will

cause minor disagreements. If, however, a person fails to agree with others about the very basic kinds of facts that are part of the *reality constraint*, or about the kinds of explanations for actions that are taken to be minimally intelligible, she will not be able to interact with other people in the ways that characterize personhood.

This provides a broad outline of the Narrative Self-Constitution View. The next section considers what this view says about personal identity in DID patients.

Narrative and DID

At first glance, it may seem as if the Narrative Self-Constitution View would have the implication that there are several distinct persons present in a DID patient. Each alter, after all, seems to have a narrative self-conception of her own, distinct from that of the other alters. Even if there is leakage of skills or some forms of memory, the autobiography with which each alter operates in the world is different. Each has her own sense of how old she is, what she is like, what she has done, who her friends are, what her profession is, and so on. To the extent that we find the normative constraints of narrative self-constitution operating, they are operating *within* an alter.

Things are not quite so straightforward, however, and this is not the whole story the Narrative Self-Constitution View has to tell about these cases. For one thing, it is crucial to note that the individual alter narratives are clearly and dramatically deficient with respects to the norms of autobiographical narrative. This is something of which the patient herself often complains. There are periods of blackout and gaps that cannot be filled in. An alter may suddenly find herself in a strange place with no awareness of how she got there or facing implications of the actions of another alter which are now attributed to her. The kinds of seamless interactions usually taken for granted in daily life are not regularly possible for the alters because they cannot count on the degree of continuity of experience or *agency* that underlie these everyday transactions. The fact that "someone else" has controlled the body to which an alter "returns" after a hiatus makes the standard kind of person-constituting narrative impossible.

This does not, by itself, always mean that the alters are not individual persons. As explained above, an identity-constituting *narrative* is not required to be perfectly accurate or complete; all that is required is that the individual recognize the norms of accuracy or completeness as legitimate goals. This is something that at least some of alters in most cases of DID clearly do; they are in fact deeply distraught by the disruptions of narrative continuity and lack of coherence in their lives. Nevertheless, the narrative lacunae within the individual alter narratives are usually sufficiently profound that they interfere markedly with the ability to engage in the kinds of interactions that characterize and define personhood in the sense at issue here. This is one reason the condition is considered pathological.

There is, moreover, another feature of DID which is directly relevant to questions of *personal identity*. That is the fact that there is another perspective, external to that of any of the individual alters, from which all of the alters are most naturally construed to be parts of a single (albeit atypical and disjointed) life narrative. Whatever the outcome of debates on the etiology of the disorder, from the therapeutic perspective the story is one in which a single person presents as psychologically fragmented. On the standard picture, it is a story of someone with a certain kind of susceptibility who is traumatized at a crucial life stage and protects herself by compartmentalizing her psychological life and dissociating from painful stimuli. The various alters are seen as pieces of the single person who take on different emotional jobs, and the hope is that the parts can be reintegrated so that the person can be whole again. This is equally clear, if not clearer, when the disorder is seen to be an artifact of suggestion. Here the narrative is one of a single vulnerable and impressionable person whose psychological life becomes disordered as a result of therapeutic suggestion or media hype.

It is worth noting as something of an aside that questions of etiology interact with the Narrative Self-Constitution View in many interesting ways. Among other things at issue in the debate over this aspect of DID is the question of whether those who claim recovered memories of abuse are meeting the *reality constraint*. The traditional view assumes that in most cases they are, while skeptics about the condition assume that most recovered memories are confabulation. There are many fascinating questions to be considered about the implications of this dispute, and these are worthy of careful study. They are, however, somewhat orthogonal to the issues currently under consideration. Whichever position one takes on the question of the origins of the phenomena associated with DID, there is a natural third-personal narrative of a single person who suffers some kind of psychological event that leads to symptoms of disorder and division. To the extent that the therapeutic goal is the production of a unified and integrated whole, this is a story of a single person with a psychiatric disorder rather than of several different people who happen to share a body.

The situation in DID thus seems to be one in which there is a sharp disconnect between the first-personal narrative and the third-personal narrative. The alters understand themselves as distinct individuals with their own biographies, whereas from the outside a single biography of trauma (or suggestion) leading to psychological disorder is more natural. The division is not, of course, as clear-cut as has been suggested so far. First-personal and third-personal perspectives always infect one another; that is the very nature of *personhood*. Those who interact with DID patients will likely not be able to *simply* see the patient as a single individual, since different alters must be interacted with as if they were distinct persons. And while the patient might not *experience* herself as a single person in the standard way, given a diagnosis of DID, she (at least some of the alters) may well *see* herself as a single individual with a rare disorder. We thus need a more complex description of the kind of disconnect between first- and third-personal perspectives in DID to fully understand how the Narrative Self-Constitution View analyzes this phenomenon.

It will be useful, for these purposes, to look at some similarities and dissimilarities between DID and non-pathological multiplicity. It has long been recognized in both philosophy and psychology that it is standard for humans to have psychological lives that are fragmented and compartmentalized in various ways. We experience the world differently (and so behave differently) in different contexts, in different moods, and at different life phases. According to the Narrative Self-Constitution View, the accomplishment of constituting oneself as a person involves recognizing this fact and, in a particular way, compensating for it. In non-pathological cases, persons recognize the different perspectives they experience as one and all their own and so recognize themselves as bearing some responsibility for making them cohere, or at least coexist. This, in turn, leads to the phenomenological and behavioral changes characteristic of narrative self-understanding.

An example may help. In Elliot's *Middlemarch* (1985), the narrator describes the state of mind of Dr. Lydgate during his impetuous and ill-fated plan to propose to an actress with whom he has fallen madly in love: "He knew that this was like the sudden impulse of a madman – incongruous with his habitual foibles. No matter! It was the one thing which he was resolved to do. He had two selves within him apparently, and they must learn to accommodate each other and bear reciprocal impediments." (p. 182) Lydgate has "two selves" – the madly infatuated lover and the responsible doctor – but he knows that he has these two selves and experiences them both as *him*self. He is the overarching whole within which these selves reside, and their conflict is internal to *him*. Since these selves are both part of Lydgate they need to "learn to accommodate each other and bear reciprocal impediments." This means, among other things, that the desires, proclivities, and goals of each put constraints on those of the other. Lydgate does not simply suppress the pursuit of the lover nor does he allow it to get to the point where the rational doctor is crowded out entirely. Even in the throes of passion, he recognizes himself as a single, complex being and works to create a coherent *narrative* that involves both of these selves.

That Lydgate thinks of himself in this way shows that he has internalized in a particularly deep way the third-person perspective which sees him as a single individual. Others see him as a single person, despite the very different inner experiences he has, and this leads him to understand himself as a single person in a way that changes and constrains the vicissitudes of his inner life. The phenomenology of his infatuation and his responses to it are all conditioned by the fact that it is experienced as part of a larger life which includes both the lover and the responsible doctor. The effect here is much the same as that described earlier in which the experience of disembarking from an airplane is conditioned by the larger story within which it occurs. It is this kind of deep internalization that is missing in DID patients. They may (or may not) come to *think* of themselves as single individuals, but they do not *experience* themselves as such; the attitudes, experiences, and actions of the alters do not interact with and change one another. It is possible to see them as parts of a single life story but only, as it were, from an external perspective.

Applications and Insights

The previous section provided an overview of the way in which the Narrative Self-Constitution View can be used to analyze questions of identity in cases of DID, but it has not yet provided an answer to the original question about the number of persons encountered in encountering a DID patient. In the end the Narrative Self-Constitution View delivers no straightforward judgments about this question. On the one hand, each alter seems to have something like a personal *narrative*, and this suggests that there are multiple persons alternating control of a single body. The narratives of the alters are, however, necessarily gappy and deficient, and from the third-person perspective, there is a natural single-life narrative to tell about an individual with a fragmented psyche. This suggests that there is a single person present who is suffering from a particular psychopathology. The third-personal narrative is not a standard life story for a person, however, since it involves an anomalous degree of fragmentation and incoherence. Because of this, and because the first-personal and third-personal narratives do not mesh in the way that is typical for human lives, neither the individual alters nor the human in whom they alternate present an unproblematic life narrative. From yet another perspective, then, it seems as if there is *no* whole person present.

The Narrative Self-Constitution View thus helps to clarify exactly why it is so difficult to say how many persons are present in such cases. It also illuminates the role of embodiment in personal identity. The difficulties that arise with the narratives of DID patients stem from the fact that we expect a certain kind of narrative coherence within a single *human* life. There are good reasons for this constraint. Personhood, as understood here, is defined in terms of the ability to interact with others in the particular complex ways that typify human life. These interactions usually require us to be able to quickly identify those with whom we are interacting and to reliably make certain kinds of broad predictions about what information they are likely to have and how they are likely to behave. Since persons act through and with their bodies, moreover, they need to be able to count on a large degree of regular control over what their bodies do if they are to be effective agents. Embodiment must be taken into account when thinking about *personhood* and *personal identity*, and this is something that those who define persons as subjects and agents do not always fully appreciate. This does not mean that personal identity can or should be defined directly in terms of biological continuities, however (e.g., Olson 1997). Merely being a single human being does not make one a single person. Personal unity must be accomplished through the development of a unified self-narrative that shapes one’s experience and behavior; the role of embodiment is to delimit what can and must be included in such a narrative if it is to be truly person-constituting.

While the Narrative Self-Constitution View does not provide a simple answer to the question of how many persons are present when we encounter a DID patient it can, nevertheless, provide a rich and valuable theoretical apparatus which can be fruitfully applied to the many practical puzzles this disorder engenders. As an example, consider the question of the assignment of responsibility. Questions

frequently arise about whether one alter should be held accountable for actions taken by another. The force of these questions can be seen in legal quandaries involving criminal cases in which the defendant is understood to have a legitimate diagnosis of DID. Behnke (1997) describes three different legal approaches that have been taken to this problem. One holds that individuals with DID are generally not responsible for their crimes because the alters are enough like persons to be treated like persons. If the alter who committed a criminal act is sufficiently person-like to be held responsible, according to this position, then alters who have no knowledge of or role in the crime must also be treated as persons, and it is unacceptable to punish them for what they did not do and could not control. At the other extreme is the view, defended by Behnke himself, that we must distinguish between "person" and "personality" and recognize that it is persons rather than personalities that act. For this reason, he thinks that defendants with DID generally can be held responsible for criminal actions. While it is true that we are confronted with divided personalities, he says, there is only one *person* present, and there is little doubt in most cases that that person is capable of taking action for which she is rightly held culpable. There may be, for instance, extensive planning or calculated attempts to evade detection. In between these poles is the approach that takes the host, or dominant, personality to be the individual relevant to the assessment of criminal responsibility; if the host personality was not involved in the planning and execution of the crime, the view says, the individual should not be held culpable.

Common to all three of these approaches is an attempt to locate the person or persons involved in the crime. The first extreme sees each alter as a person, the second sees the human as a whole as the person, and the middle position sees the host personality as the person. If the Narrative Self-Constitution View is correct, however, this general strategy is mistaken. The alters *are* person-like in respects that are typically connected with *agency* and responsibility, and in some ways, perhaps, the host personality more so than any of the others. But actions *are* undertaken through human bodies, and the human body on trial is the same one allegedly involved in the crime. Rather than trying to resolve these competing pulls, the Narrative Self-Constitution View suggests that we recognize DID as an impairment of *personhoo*d that makes it impossible to find a paradigmatic moral agent. The question we thus need to ask is exactly what impact this particular kind of impairment of personhood has on the relevant forms of agency and hence on the assessment of moral or criminal responsibility.

This approach is in some ways like another defense sometimes offered in criminal trials of DID patients which argues that such patients should not be held criminally responsible for their actions either because the action is involuntary or because of defects in mens rea. This approach basically sees the defendant as a single person who is not responsible for her actions. This position also does not seem quite right either, however. As Behnke (1997) puts it, "the problem for criminal courts is that neither involuntariness nor insanity speaks clearly to the central feature of MPD [DID]: dividedness" (p. 392). The kind of impairment of *personhood* found in *DID* does not undermine agency in the way that brainwashing

or psychosis would. At the time of any particular action, the individual actor is likely to be in control of her behavior and to be able to distinguish right from wrong and reality from fantasy to the extent usually necessary for criminal culpability. The impairment is more subtle; it has to do with the inability to put together a coherent inner narrative that corresponds to the history of a single human animal.

Recognizing this problem does not offer an immediate solution to the question of how to assess moral or legal responsibility in cases of DID, but it does show us where to look to think productively about these cases. The puzzle arises because it looks for all the world as if there is a minimally competent agent acting locally at the time a criminal action is taken, but there nevertheless seems to be a problem of agency because of the way in which agency *at a time* is impacted by failures of coherence *over time*. The question of the connection between agency at a time and coherence over time has received some attention from philosophers, but not as much as it should have. The Narrative Self-Constitution View offers a particularly useful framework for investigating these issues by showing the ways in which diachronic and synchronic aspects of personhood and agency are interconnected, and so how failures of coherence over time can affect agency at a time. This is just what is needed to determine agency and responsibility in these cases. There is much work to be done to develop the understanding we need to answer these questions fully, but the Narrative Self-Constitution View offers a path to getting that work done.

Conclusions and Future Directions

DID troubles our ordinary way of understanding and individuating persons. While it is tempting to try to ascertain how many persons are present in a case of DID, it is more fruitful instead to recognize that there is no straightforward answer to this question and to find a theoretical framework for understanding the different ways in which this disorder interferes with paradigmatic personhood, drawing the practical implications of and potential remedies for such impairment. The *narrative* approach promises to provide such a framework.

Impact of Brain Interventions on Personal Identity

Abstract

Some of the main ethical concerns with brain interventions are related to psychological changes that may alter persons in morally significant ways. This chapter reviews neuroethical attempts at assessing brain interventions by describing them as having an impact on the identity of persons. By discussing clinical case reports involving deep brain stimulation in the treatment of Parkinson's disease, different meanings attributed to the concept of personal identity in the bioethics literature are disentangled. The concept of forensic personhood is introduced to show that some possible effects of brain interventions are unambiguously detrimental in that they end the affected person's existence in an important sense. The same holds true for changes in personal identity where a person has changed to such an extent that, eventually, one does not seem to be faced with a person with different characteristics, but with an altogether different person. As well, narrative accounts of personal identity are

discussed in some detail as they have multiple normative implications for the assessment of the psychological effects of brain interventions, ranging from legal and ethical to clinical and methodological consequences.

Introduction

Some of the main ethical concerns with brain interventions are related to psychological changes that may alter persons in morally significant ways. While the risk of severe psychological adverse effects is not unique to brain interventions (cf. Lipsman et al. 2009, p. 376), such interventions are particularly likely to provoke fears about radical changes to a person's frame of mind. This is because these interventions seem to have a direct impact on the biological substrate of personal identity. It is beyond the scope of this chapter to review the rich philosophical debate on whether it is necessary to refer to neurobiology to effectively address the question of whether a person remains the same person over time in spite of certain psychological changes. Rather, the focus here is on distinguishing different ways in which a person's existence may be threatened by brain interventions. As only some of these threats can properly be described as involving genuine changes of personal identity, these conceptual clarifications should help disentangle the different meanings attributed to the concept of personal identity in the bioethics literature. Subsequently, a particular strand of theorizing that addresses issues of personal identity in narrative terms will be introduced in more detail. Since narrative approaches to identity appear particularly applicable to clinical cases involving untoward consequences of brain interventions, it should be clear why they came to play such a prominent role in relevant neuroethical debates.

The conceptual analysis will be advanced by discussing clinical case reports involving the application of deep brain stimulation (DBS) in the treatment of Parkinson's disease (PD) (cf. ▶ Chap. 35, "Deep Brain Stimulation for Parkinson's Disease: Historical and Neuroethical Aspects"). The reason for focusing on DBS in PD is not that this neurotechnical intervention is particularly threatening for personal identity nor that it would involve any special risks for the integrity of persons. Rather, this focus is motivated by a desire to limit the empirical complexities, as the conceptual matters are complicated enough. Issues of personal identity are regularly brought up in the ethical assessment of neurosurgical interventions in general (cf. ▶ Chap. 59, "Ethics in Neurosurgery") and invasive neurotechnologies like DBS in particular (cf. ▶ Chap. 34, "Ethical Implications of Brain Stimulation").

In the early days of neuroethics, neural grafting (cf. ▶ Chap. 52, "Ethical Implications of Cell and Gene Therapy"), e.g., the transplantation of small amounts of fetal brain tissue for the treatment of PD, was the most frequently discussed threat to personal identity (Boer 1994). In recent years, DBS has replaced neural grafting as the prime example of a brain intervention that might cause changes in personal identity. This shift can be explained by the fact that invasive brain stimulation techniques

have made significant progress in a short period of time, moving from small case studies to clinical practice. DBS has not only been established as an effective and reasonably safe therapy for several neurological disorders, but it is also increasingly applied in the treatment of severe psychiatric disorders (cf. ► Chap. 39, "Ethical Objections to Deep Brain Stimulation for Neuropsychiatric Disorders and Enhancement: A Critical Review"). With the increasing use of DBS, anecdotal evidence has accumulated confirming the potential for deep and sometimes disturbing psychological impacts. Some of this evidence will be reviewed carefully before turning to the conceptual question of how the observed changes can be most appropriately described.

Two Clinical Cases of DBS in PD

Case report 1: In a Dutch case, described by Albert Leentjens and colleagues (2004), a 62-year-old male patient developed a manic state after 3 years of stimulation of the subthalamic nucleus (STN) for severe PD. His psychiatric symptoms included megalomania and chaotic behavior that had resulted in serious financial debts. The patient did not respond to treatment with a mood stabilizer and so was admitted to a psychiatric hospital where he was deemed incompetent. By adjusting the stimulation parameters, it was possible to restore his decisional capacity. Unfortunately, this improvement resulted in a worsening of his motor symptoms. It was impossible to strike a satisfying balance between alleviating the psychiatric and the neurological symptoms, and so the patient ultimately was presented with a terrible choice: He could be admitted to a nursing home, physically disabled, but in good mental health, or he could be committed to a psychiatric ward because of his mania, but with good motor function. With the stimulator turned off, and the patient deemed competent, he chose to be admitted to a psychiatric hospital.

Case report 2: A much less dramatic, but no less important, case involving DBS for the treatment of PD has been reported by Michael Schüpbach and colleagues (2006). A 48-year-old male accountant, whose PD symptoms were successfully alleviated by DBS, experienced a grave marital conflict in the year following the initiation of DBS. Before receiving DBS, the patient was dependent on his wife for all tasks of daily living. Following DBS, he regained self-confidence and this resulted in marital strife. The authors describe the ensuing conflict by quoting the patient and his wife:

> "I want to recover my social standing and establish new relationships outside my couple. During all these years of illness, I was asleep. Now I am stimulated, stimulated to lead a different life." Confronted with the radical change in her husband's behavior, his wife became depressed: "Ever since the operation, I feel lost. Before, when he was sick, we were a perfect couple. Now, he wants to live the life of a young man, go out, meet new people, all of that is intolerable! I would rather he be like he was before, always nice and docile!" The patient persisted in his desire for change: "All these years I allowed myself to be carried like a child, because I didn't have the means to fight. That period is over, I want to get back the position I left open. I am going to take my life in hand, my life before PD." (Schüpbach et al. 2006, p. 1812)

These two case reports illustrate the wide range of impacts that DBS can have. One important difference between the two cases concerns the causal link between the intervention and the outcome. The problematic consequences experienced by the patient in the first case can be causally attributed to brain stimulation in a more immediate way than in the second case. The manic condition of the first patient is quite obviously a direct effect of DBS, as it can reliably be altered by initiating or stopping the stimulation. With the second patient, turning off the stimulator could return him to his previous neurological state, but this probably would not resolve the conflict with his wife (which makes the psychological consequences of DBS appear problematic in the first place). The marital problem has been caused by brain stimulation in some sense, but for this cause to take effect, a whole range of mediating psychosocial factors had to fall into place. As these factors can’t be made to disappear just by stopping DBS, the problematic sequelae may well persist even if the stimulation is stopped.

A second important difference between the two clinical examples concerns the different perceptions of the resulting change(s). As regards the first patient, the psychological change induced by DBS is clearly to be considered an *adverse* effect of stimulation (even if the patient enjoyed himself in his manic state – i.e., if he did not personally experience his state of mind or chaotic behavior as problematic). With the mania the patient loses something that is so universally and strongly evaluated as a “good” that the resulting state will be considered detrimental irrespective of its possible appreciation by the patient (cf. Schechtman 2009, p. 70). This “good,” of course, is the capacity to decide what is in ones best interest and, at the same time, what is acceptable for others in the light of widely shared normative standards. In contrast, the second patient’s rekindled lust for life does not seem to bear the hallmark of psychiatric abnormality. The patient’s appreciation of his regained independence seems perfectly understandable and healthy. In fact, if the patient’s psychological transformation did not cause so much discomfort to his wife, one would have no reason for moral suspicion regarding the effects of brain stimulation in this case.

Ways of Questioning the Identity of Persons

Is it appropriate in either of the two cases to describe the changes as changes in personal identity? Walter Glannon analyzes the first case (involving the Dutch PD patient) in two papers (Glannon 2009, 2010) focusing on patient autonomy in general, and more particularly on whether a patient can give valid consent to a treatment that deprives him of the capacity to revise this decision in the further course of treatment. In passing, Glannon addresses the suspicion that the patient is undergoing identity change when switching into the manic state. According to Glannon, this question must be answered in the negative if one presupposes a concept of *numerical* identity. Glannon maintains that continuity in “a minimal set of physical and psychological properties” suffices to make sure that an individual remains the person he or she is in the sense of numerical identity (2009, p. 291).

If, on the other hand, one presupposes a concept of *narrative* identity, then the crucial question is whether the disruption in the patient's personality caused by DBS, as represented in his "distinctive autobiography," is severe enough to claim that, under its influence, the patient becomes a different person (ibid.).

The Forensic Account of Personhood

The basic assumptions of narrative views of personal identity will be addressed in more detail below. Before doing so, however, it is worth considering a third possible description of the change induced by DBS in the first case. In this case, the transition into the manic state is characterized by a severe loss of decisional capacity – which is not just any kind of personality trait. This loss renders the patient legally incompetent to the point that institutionalization is warranted. Under the influence of DBS, the patient can still act, but his actions are no longer autonomous in the important sense that he can no longer be held fully responsible for them. According to a long-standing tradition in philosophy, going back to John Locke, this amounts to saying that DBS deprives the patient of an essential feature of personhood. Locke considers "person" to be a "forensic term" whose primary function consists in "appropriating actions and their merit" (Locke 1975 [1689]: §26). Hence, a human being who, for whatever reason, lacks the requisite psychological capacities to engage in moral and legal practices like giving promises or entering into other sorts of binding commitments cannot be regarded as a person in the proper sense (cf., e.g., Merkel et al. (2007: 5.3.2) for a detailed account of the cognitive, emotional, and motivational requirements that such a view of personhood entails). Following Locke, Marya Schechtman proposes to distinguish a further possible sense of identity, namely, "forensic personal identity" (2009, p. 68). According to Schechtman, the "judgment that someone is not (or not fully) a forensic person relieves him of certain kinds of responsibilities and commitments" (2009, p. 69). What such a judgment does not entail, however, is the denial of rights (in particular the right to respectful treatment) that need to be respected in relation to any human being, regardless of whether he/she is a person.

This account of personhood in terms of moral agency necessitates the distinction between a loss of personhood on the one hand and genuine cases of (forensic) identity change on the other hand. Schechtman exemplifies the former possibility by referring to the gradual fading away of forensic personhood during the progression of dementias such as Alzheimer's disease which can, eventually, lead to a state in which a patient may no longer be held accountable for his actions (2009, p. 71). Schechtman's discussion of the second possibility, personal identity change, is based on a (hypothetical) clinical case involving DBS for a Mr. Garrison for the treatment of advanced PD – a case that bears many similarities to our second case of the reinvigorated husband.

In Mr. Garrison's case, DBS has the wanted side effect of relieving him of apathy syndrome which he developed during PD progression (2009, p. 77).

Mr. Garrison's lifted spirits provoke marital problems. Under the influence of DBS, he pursues interests and develops passions that, at least as judged by his wife, do not fit the person that Mr. Garrison was before brain stimulation. For instance, he starts spending money on charitable causes, thereby threatening plans that he and his wife had made in caring for their retirement. Also, under the influence of DBS, he is outgoing and gregarious, where once he was shy and introverted. Despite the considerable discontinuity in Mr. Garrison's personality before and after DBS, according to Schechtman it would be wrong for his wife to acquit herself of her duties as a spouse by making claims to the effect that she did not marry the person that Mr. Garrison is under the influence of DBS. Schechtman considers the fact that Mr. Garrison's radical change of attitudes can at least to some extent be attributed to the influence of DBS as a kind of mitigating factor, because "it does not seem entirely fair to hold Mr. Garrison to the same standards of consistency that we would expect from someone who had not had such treatment. It does not seem obvious that he should be held responsible for commitments made before the personality change, and to this extent it seems right to treat him as a new forensic person" (Schechtman 2009, p. 78).

Mr. Garrison's case illustrates how recognizing a change in forensic personal identity can be complex and ambiguous. At least with regard to the practical commitments of a married couple, any single decision as to whether such an identity change occurred seems to be very much context dependent and, ultimately, open to negotiation. When the stakes are higher, however, as for instance in cases of potential legal liability, less ambiguity will be tolerated in deciding issues of forensic personal identity. For example, if Mr. Garrison committed murder before receiving DBS, in all likelihood the psychological discontinuities brought about by DBS would not be judged severe enough to excuse the stimulated Mr. Garrison from criminal liability for a crime that could not be attributed to any other human being but him. Were he careless enough, for instance, to testify that he perfectly understood why the person who used to reside in his body before DBS murdered the victim and that he himself would do the same if he had the chance, then any jury would probably feel entitled to conclude that there is sufficient personal continuity between the accused person and the person who committed the crime to justify Mr. Garrison's conviction in spite of his alleged identity change. On the other hand, matters might be different if Mr. Garrison had no memory of the crime.

Reinhard Merkel and coauthors (2007, p. 270) consider cases of dissociative amnesia as the most clear-cut examples of personal identity change. If a person loses all his autobiographical memories, as can happen with complete retrograde amnesia, it may seem appropriate to say that, in a significant sense, the earlier person's existence has come to an end. If the individual who suffers from amnesia still fulfills the criteria of personhood, then he may legitimately claim to be a new person who has to start his life from scratch. Merkel and coauthors admit, however, that even in such extreme cases of psychological discontinuity, a person would not necessarily be acknowledged as a *new* person, "but rather as a person with a certain form of dissociative disorder" (2007, p. 270).

Normative Implications of the Concept of Forensic Personhood

Any answer to the question of whether a change in personal identity may result from a brain intervention obviously has to presuppose a theory of personhood. For without knowing what persons are, it is impossible to say under which circumstances a person comes to an end and another emerges. With the concept of forensic personhood, persons essentially are moral subjects who can take responsibility for their actions. Using this conceptual framework, the special tragedy of the Dutch patient lies in the fact that by deciding to receive DBS he is deliberately entering a state in which his accountability is reduced to such an extent that he can no longer be recognized as a forensic person. This case is vexing in that the patient under the influence of DBS in most respects still behaves like a person. It is certainly easier to acknowledge the loss of personhood in human beings who are in long-lasting states of unconsciousness. These difficulties notwithstanding, if moral agency is at the heart of personhood, then the person who the Dutch patient used to be prior to receiving DBS has ceased to exist. Only by making a clear distinction between persons and human beings can theories of forensic personhood also leave room for the possibility that the human being who used to be recognized as a particular person before an intervention into her brain continues to live as a different person. While indisputable cases of forensic identity change are hard to find, the pivotal issues are whether and to what extent a person after a brain intervention is both willing and able to take responsibility for previous actions and live up to the commitments and consequences that follow from those actions. Issues concerning personal identity change after brain interventions will only be raised if a patient severely fails to fulfill the expectations of others related to the commitments of the person he used to be before an intervention into his brain.

It is useful to make a clear conceptual distinction between cases in which a brain intervention like DBS leads to (a) the loss of personhood, (b) a change of (forensic) personal identity, and (c) other more or less profound psychological sequelae, so as to offer a nuanced normative assessment of these different classes of consequences. Any medical intervention that regularly leads to consequences of either type (a) or (b) merits the highest ethical scrutiny as in these instances the person’s existence comes to an end – an event that is sometimes called “psychological death.” Nevertheless, such interventions can be justified as legitimate treatment decisions if foregoing them might lead to similarly grave consequences. The physicians who turned the stimulator back on after the Dutch patient consented to the continuation of DBS seem ethically justified in what they did, only because it was the patient himself who made the decision. It would be impossible to decide for someone else whether it is best to be of sound mind in an immobilized body or to retain motor control over ones actions at the cost of losing the ability to take full responsibility for those actions.

Because of the normative salience that any impact on personhood and personal identity acquires in a framework of forensic personhood, it would also seem justified to require that it should never be among the goals of any intervention in the brain to bring about consequences of type (a) or (b). Such consequences can be

envisaged as grave risks associated with desperate treatment decisions, but they should never be viewed as possible benefits. Compared to these strong normative claims, we are entering the realm of ethical ambiguity when assessing the cluster of possible psychological changes provisionally lumped together under (c). In order to establish further meaningful normative distinctions for the assessment of possible psychological effects of brain interventions, we need to review the conceptual resources of narrative theories of personal identity.

Narrative Approaches to Personal Identity

As noted above, philosophers who champion a narrative approach to personal identity tend to draw a sharp distinction between narrative and numerical identity (cf. also DeGrazia 2005, p. 78 and Focquaert 2009, p. 2). To properly grasp this distinction, one has to understand that two quite different concepts of a person's "identity" are in play. A person's numerical identity is at stake when the task at hand is to make sure that a person at one point in time is the same person at another point in time. Here "identity" is taken to refer to the logical relation of identity (cf. Merkel et al. 2007, p. 195). Theories of numerical personal identity thereby answer the *reidentification* question by specifying conditions under which a person can be correctly reidentified as the same person in spite of her having changed over time in various ways. According to Schechtman (1996), who developed a narrative approach to personal identity that is particularly influential in bioethics, an alternative perspective on a person's identity is provided by the *characterization* question which is asking "which beliefs, values, desires, and other psychological features make someone the person she is" (Schechtman 1996, p. 2). The characterization question addresses a person's identity in roughly the same meaning as implied in talking about a person suffering an "identity crisis" (ibid., p. 74), giving rise to questions like "Who am I really?" A person's identity, in this sense, can be described by a set of characteristics. On this view, "identity change" is shorthand for changes in a person's characteristics that are profound and/or pervasive enough to justify the claim that the person is no longer the same in an important sense in spite of his numerical identity being preserved. The characterization question offers a sound way of interpreting sentences such as "this person has changed her identity" or "that person lost his identity" – interpretations that do not make sense if personal identity is understood numerically. From the point of view of reidentification, talking about a change of personal identity implies that a person has undergone a process of change to a degree that, eventually, we are not faced with a person with different characteristics, but with an altogether different person. Taken literally, however, the sentence "this person has changed his identity" presupposes one person's continued existence, albeit with different identities at different points in time.

Viewed in this way, it is misleading to contrast numerical and narrative identity, because the former concept of personal identity is more fundamental than the latter. Rather than providing an independent perspective on what a person's identity is, the

characterization question presupposes an answer on the reidentification question (cf. Merkel et al. 2007, p. 193; DeGrazia 2005, p. 114). Before making meaningful intrapersonal comparisons of a particular person's characteristics at different points in time, one needs to know that the person remains the same in the numerical sense over the whole period of comparison. Thus, it is somewhat inadequate to talk about "narrative identity" next to "numerical identity," because this way of putting things conceals that the two concepts are operating on different levels. Rather than viewing narrative accounts of personal identity as dealing with a special kind of identity, it may be more helpful to describe them as representing a particular approach to questions related to personal identity. While most proponents of this approach restrict their narrative theorizing to the characterization question, Merkel and his coauthors (2007: 5.4.5) propose a narrative approach to personal identity that is supposed to provide an answer to the reidentification question as well. They avoid the term "narrative identity" altogether, instead calling their answer to the characterization question a narrative account of *personality* (2007: 5.4.4). This seems like an interesting suggestion in view of the fact that, as will be shown subsequently (sub 4.2), the assessment of personality changes is a particularly important area of application for narrative accounts of personal identity.

Basic Assumptions of Narrative Accounts of Personal Identity

Just what is "narrative" about narrative approaches to personal identity (cf. also the ► Chap. 24, "Dissociative Identity Disorder and Narrative")? This is not the place to delve deeply into the dazzling diversity of narrative approaches to the "self" advanced by philosophers, sociologists, and social and developmental psychologists (cf. Schechtman 2011 for a review). Instead, the focus here is on common features of narrative approaches to personal identity that surface in discussions of neuroethical issues. Common to such accounts is the idea that persons or selves are *constituted* by the stories they tell about who they are. That is, listening to autobiographical narratives is not just an epistemic strategy to find out who a person is. A person's identity does not simply *express* itself in a self-narrative, rather it is *formed* in the process of autobiographical storytelling. Persons are making sense of themselves by structuring their lives in narrative ways or, as Schechtman puts it, "selves are inherently narrative entities" (2011, p. 395).

Narrative accounts of personal identity need to come to terms with the fact that self-narratives are fraught with mistakes. The stories people tell about who they are include both inadvertently erroneous and deliberately deceptive statements. Hence, such stories do not reveal who a person really is but (at best) only how she conceives of herself, i.e., her self-concept. Schechtman attempts to bridge the epistemic gap between a person's self-concept and any trustworthy account of who the person really is by introducing the *reality constraint*. According to this constraint only those parts of a person's self-narrative which "fundamentally cohere with reality" will be recognized as identity constituting (Schechtman 1996, p. 119). Other proponents of narrative accounts of identity offer different solutions to the

problem of (self-)deceptive self-narration, but they all agree that some kind of reality check for autobiographical storytelling is required (DeGrazia 2005, p. 85; Merkel et al. 2007: 5.4.4).

A further fact that may seem to challenge the basic idea of narrative approaches to personal identity is that people differ widely in their propensity to tell stories about themselves. Some people just do not like to spend many words on characterizing themselves. Should they be viewed as having "no (narrative) identity" or at least as having "no well-developed identity"? – Schechtman avoids implausible conclusions of this kind by pointing out that a person's self-narrative is not only articulated in stories she explicitly tells to others, rather: "Much of our self-narration is expressed in the way we think, the way we live, and the kinds of explanations we feel called upon to give others" (Schechtman 2011, p. 407). The fact that people do regularly demand explanations from each other with regard to the way their behavior may or may not fit with their perceived self-concepts lends credence to the *articulation constraint*. This constraint requires that, at least when prompted to do so, a person should be able to "account for her actions and experiences by showing how they are a part of an intelligible life story with a comprehensible and well-drawn subject as its protagonist" (Schechtman 1996, p. 114). Alternatively, the articulation challenge can be met by highlighting the social interplay in which self-narratives are formed. After all, whenever self-narratives are actually told to others, the listeners are likely to play an active part in revising the narrative by adding their own material and perspective. In view of the social contribution to self-narration, and the presumed fact that our self-concepts are revealed in the way we act, not much explicit storytelling seems to be required on the part of a person for the constitution of a narrative self. Merkel and coauthors confirm this point by claiming: "even the most reticent person, who remains imperturbably close-mouthed whenever others approach her with their unbidden characterisations, cannot avoid to confirm or refute the stories they tell about her through her deeds" (2007, p. 258).

The fact that self-narratives gain and change their form and content over time in an ongoing process of social exchange has obvious ramifications for the reality constraint as well. The listeners of self-narratives not only help in articulating the story of who a person is, they also keep an eye on the storyteller staying true to the facts. Beyond such basic considerations, however, the extent to which the social nature of self-constitutive storytelling is brought to bear differs significantly in the literature on narrative personal identity. For example, Françoise Baylis' "relational account of personal identity" offers an example of a narrative approach to identity that places special emphasis not only on the social, but also the cultural, political, and historical embeddedness of self-narratives. As an alternative to the *reality constraint* and the *articulation constraint* introduced by Schechtman, Baylis introduces the *equilibrium constraint*. According to this constraint, "the identity-constituting narrative is the narrative that effectively balances how a person sees and understands herself, with how others see and understand her" (Baylis 2011).

A further widely shared feature of narrative approaches to personal identity is that, at some point in their theorizing, they adopt a *principle of coherence*.

For example, Merkel and coauthors not only require that self-constituting stories, which purport to describe who a person really is (or "what her personality is like," in the terminology of Merkel et al.), should be "extrinsically" consistent with the facts but also that they "intrinsically" fulfill minimal requirements of coherence that any narrative with a claim to truth needs to meet (2007, p. 261). Similarly, Schechtman demands a high degree of coherence of narratives if they should be recognized as identity constituting, that is, such stories should obey to comparatively "conservative" standards of narrative form (1996, p. 98). Thus, even if narrative theorists need not require that a self-constituting narrative should have an overarching theme or purpose, they may still want the storyteller to at least try to make some sense of the story of his life. In assuming a narrative form, the events of one's life are placed in a comprehensible sequence. Moreover, in arranging the story line, not only the past is taken into account, but also plans for future development are being made. The importance of such projects of self-creation for the narrative constitution of the self has been stressed by Jonathan Glover (1988) and fruitfully applied to bioethical issues by David DeGrazia (2005: Ch. 3).

In conclusion, while narrative approaches to personal identity initially may appear to be rather "liberal" in that they do not come up with necessary and sufficient conditions for persons to be and remain who they are, a closer look reveals that some accounts place substantial constraints on the kinds of self-narration that can be properly regarded as constituting a person's identity.

Normative Implications of Narrative Accounts of Personal Identity

Several proponents of narrative accounts of personal identity put their theories to test by assessing the ethical concerns raised with regard to the psychological effects of brain interventions in general and DBS in particular. As the earlier discussion of Schechtman's evaluation of Mr. Garrison's fictive case already implied, she considers DBS to pose a general threat to personal identity by causing "a disruption of the narrative flow of a life" (2010, p. 137). The reason why DBS appears as a mitigating factor to Schechtman in deciding about the responsibility of Mr. Garrison for commitments of his earlier "unstimulated" self is that the rapidity with which DBS "mechanically" induces psychological changes runs afoul of the articulation constraint. While Mr. Garrison may try to establish narrative continuity with his self before DBS by offering reasons for his changed ways of thinking and behaving, doubts may always lurk in the background as to whether they are the real reasons for his psychological changes or whether, in fact, they have been caused by brain stimulation. In a helpful manner, Schechtman's narrative self-constitution view not only offers a reason for ethical scrutiny with regard to DBS, but also hints at possibilities to avoid the threat that DBS may pose to personal identity: "Since narrative is a dynamic notion, continuity of narrative is thoroughly compatible with even quite radical change. The important thing is that the change be understood in a way that makes it part of a coherent personal narrative, one that patients and their close associates can see as, overall, self-expressive and self-directed"

(Schechtman 2010, p. 138). To the extent that the associates of a patient are able to offer him interpretations of his psychological transformation that make sense in the overarching narrative framework of his life, they can help to avoid damage to his identity.

Baylis, whose relational account of personal identity has many commonalities with Schechtman's narrative theory, also acknowledges that "DBS can be a uniquely disruptive experience resulting in dramatic changes in behavior, mood and cognition" and that these changes can have a major impact on personality (Baylis: 2011). Baylis insists, however, that changes in personality are not in themselves sufficient to warrant claims about threats to personal identity. Baylis emphasizes the dynamic nature of narrative concepts of the self and argues that if DBS is to be seen as a threat to the process of identity formation simply because it results in significant personality changes, then it would be legitimate to characterize all significant life events (both positive and negative events) such as graduation, job loss, marriage, birth of a child, divorce, and earthquake as threats to personal identity insofar as they could result in dramatic changes in personality (Baylis 2011). According to Baylis, it is only "when DBS undermines agency to such an extent that the person is no longer able to meaningfully contribute to the authoring of her own life," that it may be accurate to describe DBS as a threat to personal identity.

Our discussion of the concept of forensic personhood has shown that cases in which brain interventions lead to a loss of impulse control or other prerequisites of autonomous agency do not require an assessment in narrative terms. It may provide stronger reasons for ethical concern to describe such cases as involving a threat to the patient's continued existence as a (forensic) person, rather than saying that his narrative identity is being threatened. However, the benefit of viewing the consequences of brain interventions through a narrative lens may become more obvious if the psychological changes experienced by patients are more ambiguous than in the extreme cases in which personhood seems to be undermined. Narrative approaches to personal identity prove particularly useful in cases like our second case report which seem to involve personality changes on the part of the patient.

Personality changes pose a particular challenge for any ethical assessment of brain interventions as they are complex and hard to measure and at the same time characterized by a high life impact (cf. Müller and Christen 2011, p. 8). On a narrative account of personal identity, personality changes do not appear inherently problematic because any meaningfully unfolding life story includes profound psychological changes in the wake of successful and sometimes failing projects of self-creation (cf. DeGrazia 2005, p. 236). This seems to justify the following conclusion by Matthis Synofzik and Thomas Schlaepfer: "Thus, the ethically decisive question is not whether DBS alters personality or not, but whether it does so in *a good or bad way* from the patient's very own perspective" (2008, p. 1514; emphasis in original). Noteworthy, Synofzik and Schlaepfer arrive at this conclusion using different theoretical premises. Rather than subscribing to a narrative concept of personal identity, they rely on an understanding of personality "as a supramodal representational system with largely heterogeneous

functional and (self-)representational levels" (2008). Whatever the theoretical merits of such a "naturalistic account of the self" may be, it certainly does not offer any grounds for the ethical evaluation of personality changes (cf. Witt et al. 2011). All that may be derived from it is a principle of caution, as each and every neurotechnical intervention *can* have an impact on personality, even if it primarily aims at altering sensorimotor circuits as in DBS for PD, because among the important parts of personality are also "low-level sensory, motor or vegetative states" (ibid.).

In contrast with this plausible but rather unspecific result, thinking about personality changes in narrative terms opens up a new evaluative perspective in that not all features of a person's personality are of equal importance to her in view of her narratively constituted self-concept. For instance, it may seem less problematic to potentially alter a particular personality trait in a person for whom this characteristic plays a minor role in his self-narrative, than in someone for whom it represents a core feature of his self-concept. While the protection of such core features of personality should have high priority in risk-benefit considerations concerning brain interventions, no personality trait has to be declared sacrosanct on narrative grounds.

History of humankind is ripe with examples of people sustaining the narrative thread of their selves in spite of the most far-reaching disruptions in their life stories. Narrative accounts can provide an explanation for the individual differences in the ability to accommodate disruptive events in a stable self-concept by pointing out that self-constituting narratives may differ in their pliability because of their specific contents and because of the varying rigidity of their *narrative styles* (cf. Merkel et al. 2007, p. 260). Moreover, as the discussion of Schechtman (2010) has shown, narrative approaches may even indicate new ways of handling cases of "identity crisis" after brain interventions in that it may be helpful to mobilize "narrative resources" for their integration into a meaningful life story not only in the patient himself, but also in his significant others.

Finally, although this possibility has not been explored so far, it may be worth considering the implications which a narrative account of personal identity may have for patient information on possible psychological side effects in the consent process for brain interventions. It may turn out to be a real challenge to convey to a patient the subtle ways in which his self-concept may change in the wake of a brain intervention including, for instance, changes in his value system to the effect that even his current standards of weighing the possible consequences of treatment may change. At any rate, the physicians involved in clinical decision making for brain interventions should try to take the individual differences in the way persons conceive of themselves and of life itself into account. The currently available instruments for the psychological assessment of personality changes and the psychiatric assessment of personality disorders do not seem to pay due attention to possible changes in a person's self-concept which, according to Merkel and coauthors' "narrative account of personality" (2007: 5.4.4), represents an integral part of personality. The infinite diversity of self-narratives calls for an individualized assessment of the psychological sequelae of brain interventions.

It is thus no accident that Schüpbach and colleagues (2006), who created much interest by describing the unexpected dissatisfaction in PD patients who gained considerable relief from their motor symptoms by DBS, were among the first to employ unstructured in-depth interviews in their assessment of the psychosocial consequences of DBS. A narrative approach to personal identity thus requires that the validated quantitative test instruments for the detection of personality changes should be complemented by qualitative methods like semi-structured open interviews. These interviews should not only be conducted with the patients, but also with their relatives and caregivers, because only by taking different perspectives into account can points of disagreement be identified between a patient's self-concept and the way others conceive of her. Once again, this conclusion receives independent support from authors who themselves do not understand identity in narrative terms (cf. Synofzik and Schlaepfer 2008, p. 1515; Witt et al. 2011).

Conclusion

After brain interventions people may experience various kinds of psychological changes, some of which are more relevant for the ethical assessment of such interventions than others. According to many neuroethicists, a particularly important class of psychological effects is provided by changes that affect the identity of persons. Discussions of the possible impact of brain interventions on personal identity usually assume that such an impact is cause for concern, not hope. However, this evaluative assumption holds true only for some of the accounts of personal identity reviewed in this chapter. It seems justified as far as the numerical identity of persons is concerned. Something undoubtedly went wrong, if after a brain intervention a patient either lost one of the capacities necessary for personhood or can no longer be recognized as the same person in the numerical sense. The possibility of a person's existence coming to an end with the corresponding human being staying alive cannot be accommodated by all accounts of personal identity. In particular, those accounts that adopt biological criteria for the persistence of persons leave no room for such issues of numerical identity. The concept of forensic personhood, on the other hand, not only allows for human beings who (at different stages of their lives) cannot be recognized as forensic persons, but also makes sense of the possibility of personal identity change where two persons (or possibly even more persons as in cases of dissociative identity disorder, cf. the ► Chap. 24, "Dissociative Identity Disorder and Narrative") consecutively "reside" in the same body. As both possibilities entail the (transient or permanent) loss of something valuable, i.e., the capacity for autonomous agency, the framework of forensic personhood justifies the evaluative assumption that any impact on numerical personal identity has to be considered as a risk and never as a benefit of brain interventions.

If, in contrast, personal identity is construed narratively, then it seems implausible to assume that any change in a person's narrative identity must necessarily be for the worse. The concept of narrative identity is closely related to the concept of

personality in that both concepts can be readily employed to answer the characterization question related to persons. It can thus be understood why narrative approaches to personal identity hold a lot of promise for the ethical evaluation of personality changes occurring after brain interventions. In some sense, personality changes definitely affect who a person essentially is, which is why their assessment is so important in clinical decision making. On most accounts of personality, however, persons and their significant others may be afraid of some personality changes and welcome others. While there may be good reason to generally ban certain modifications of personality, e.g., enhancing aggressiveness, it does not seem in principle objectionable to modify personality by brain interventions. Narrative approaches to personal identity may offer guidance for risk-benefit considerations related to personality changes. Such treatment decisions are particularly challenging, irrespective of whether personality changes are envisaged as possible side effects or as the intended outcome of an intervention.

Ultimately, both approaches to personal identity prove useful for the ethical assessment of brain interventions. On the one hand, considering the possibilities of losing personhood and of (numerical) personal identity change helps identifying illegitimate goals and grave risks of brain interventions. Thinking about personal identity in narrative terms, on the other hand, suggests an ethically significant sense in which a person may change without her existence thereby coming to an end and hints at useful criteria for the assessment of such changes.

Extended Mind and Identity

Abstract

Dominant views of personal identity in philosophy take some kind of psychological continuity or connectedness over time to be criterial for the identity of a person over time. Such views assign psychological states, particularly those necessary for narrative or autobiographical memory of some kind, and special importance in thinking about the nature of persons. The extended mind thesis, which has generated much recent discussion in the philosophy of mind and cognitive science, holds that a person's psychological states can physically extend beyond that person's body. Since "person" is a term of both metaphysical and moral significance, and discussions of both extended minds and personal identity have often focused on memory, this article explores the relevance of extended cognition for the identity of persons with special attention to neuroethics and memory.

Personal Identity

Philosophical work on personal identity has involved answering two related questions: what is the nature of persons, and what criteria identify a person over time? Answering this second question, the question of diachronic identity, presupposes an answer to the first question. We need to know what persons are in order to identify them over time.

Standard views of personal identity have tended to assume, following John Locke's watershed work on personal identity in *An Essay Concerning Human Understanding*, that defining the nature of persons (or "personhood," as philosophers are apt to say) requires understanding the nature of the self, where the self is constituted by a unified continuity of conscious states. This assumption about the nature of persons underpins contemporary psychological accounts of a person's identity over time, most of which draw on Locke's own appeal to memory. The memory one has of one's self is one's narrative or autobiographical memory. Such accounts, sometimes referred to as "neo-Lockean," have held sway as the dominant view of diachronic personal identity throughout the twentieth century.

Locke himself proposed memory as criterial for tracking a person through time because he viewed "person" as:

> a forensic term appropriating actions and merit; and so [belonging] only to intelligent agents capable of a law, and happiness and misery. This personality extends itself beyond present existence to what is past, only by consciousness; whereby it becomes concerned and accountable, owns and imputes to itself past action, just upon the same ground and for the same reason that it does the present. (1690, Bk. II, Ch. XXVII, §26)

That is, for Locke, the term "person" functions to allow us to praise, to assign blame, and to hold individuals accountable for what they have done in the past.

As the passage makes clear, for Locke the designation of personhood is to be attached to a self. Given Locke's earlier discussion of the identity of the same substance, same human being, and same person over time (II:xxvii.6), it is clear that Locke takes this self to be something other than a substance or a kind of living organism. For Locke, the self is distinctively individuated over time by some kind of psychological continuity, one in which memory plays a key role.

One influential argument that Locke provides for this view turns on his introduction of a now-famous example. Imagine a prince and a cobbler, with their very different personalities, characteristics, and memory, waking up one day with the minds of each of them switched into the body of the other (II:xxvii.15). If these mind-body pairs were switched, Locke explains, then the personality and memories of the prince would be transferred into the cobbler's body. This would be a case, Locke argues, in which the prince now exists in the cobbler's body, and the cobbler in the body of the prince. The reason for this is that memory and the cognitive capacities required for memory serve the forensic function Locke attributes to personhood. Locke writes "whatever past actions it [the person] cannot reconcile or appropriate to that present self by consciousness, it can be no more concerned in than if they had never been done" (II:xxvii.26).

Despite the dominance of Lockean and neo-Lockean views of persons and their identity over time, they are not the only game in town. Theories proposing a biological criterion for diachronic identity discount the importance of psychological continuity, looking instead to the structural integrity of an organism as the basis for an individual's identity through time. Proponents of the biological criterion take an essentialist approach to the problem of identity by pursuing the question of what kind of thing humans are, basing their account of personal identity on the persistence conditions of that thing. For instance, Eric Olson (1997, 2003) argues that human beings are essentially biological organisms or human animals. Thus for Olson, tracking the identity of a person has nothing particularly to do with that person's mental states or memory. Instead, it is sufficient to know the persistence conditions of human organisms and to apply them to a person of interest in order to identify or reidentify that person over time.

Morally speaking, we ought to feel apprehensive about a view that would be willing to hold a person accountable even if its mind were unaware of the body's previous activities and, in fact, cognizant of entirely different actions. The full weight of this implication is apparent if we imagine an assailant and his or her victim switching brains. According to the biological approach, the assailant's body should be punished for the crime despite the fact that the experience of the punishment is to be added to the victim's already emotionally traumatized conscious states; the victim would remember being assaulted and then would be punished for his or her assailant's actions. Thus, if we are to preserve both the connection between person and moral blame that Locke made in viewing "person" forensically and our intuitions about this particular case, we seem drawn from the biological to the psychological criterion.

Another essentialist alternative to neo-Lockean views postulates a continuing mental substance, the identity of which may be independent of either psychology or biology. Although some version of a substantive view of personal identity may be widely accepted by the general public, such views are at best marginally represented among philosophers. The problem making this approach philosophically unpalatable is this: if the substance is not altogether lacking in psychological and biological traits, then its identification will inevitably be based on those traits, which will in effect amount to a trimmed (and likely somewhat impoverished) psychological or biological view. Thus, such a view, in order to represent a distinctive alternative, would have to postulate a featureless substance. However, as David Shoemaker has argued, "[w]e cannot track immaterial egos floating free from any particular psychological properties, so on this view we would never be justified in claiming to have re-identified anyone" (2012, Sect. 2.5).

Despite the departure of neo-Lockean views from a substance-based account of persons, their focus on consciousness and memory shares with such accounts an attempt to differentiate humans from nonhuman animals and plants by appealing to the nature of their mind or soul. Aristotle famously argued that although humans share in the nutritive and perceptive capacities of plants and nonhuman animals, the rational soul is unique to human beings. Although Locke eschews a commitment to any kind of substance as the grounds for his account of personal identity, Locke's views do

reflect the ratio-centrism that one finds in this Aristotelian tradition, as well as a certain kind of individualism about the nature of persons and their identity over time. This is because certain rational cognitive capacities are required for the autonoetic formation of episodic memories that is tied to orthodox conceptions of personal identity and personhood, and those capacities are conceptualized as depending solely on aspects of the individual herself. These forms of ratio-centrism and individualism remain features of neo-Lockean views of persons in the contemporary literature.

There are morally troubling results of both the ratio-centrism and individualism of neo-Lockean views of personal identity, especially in combination. First, such views seem to imply that individuals with certain cognitive limitations (such as, for example, a relatively limited ability to track their own personhood through time) cannot claim the right-conferring status of personhood. This resultant depersonalization of the "mentally deficient" amounts to their subhumanization and with it an abandonment of the universal ascription of fundamental human rights. Second, as a consequence of the inherent individualism of neo-Lockean views, external resources – such as other people, environments, or technologies – that may be intrinsic to certain cognitive (and other) capacities, are viewed as extrinsic to an individual's status as a person. Such external resources may causally enhance the cognitive capacities of an individual who would otherwise fall below the cognitive threshold for full personhood set by neo-Lockean views. Despite this, such external resources cannot themselves be the basis for the moral status of persons.

While the links between narrative memory, rationality, and the self make the ratio-centric and individualistic biases in psychological accounts of identity of persons over time and thus the nature of persons readily identifiable, such biases are also implicit in biological accounts of persons. Faced with the problem of specifying which of the many kinds of unified, living, persisting organisms are persons, proponents of biological views also tend to fall back on appeals to the kinds of consciousness and rationality possessed by typically human organisms. Thus, when lines must be drawn, rationality and one's intrinsic capacities become the historically authoritative boundary markers for personhood.

The Empirical Study of Mind and Personal Identity

For the most part, traditional work on personal identity in philosophy has proceeded with little reference to, let alone sustained discussion of, empirical work in the clinical and cognitive sciences. There are at least four areas, however, in which such work has been seen to be relevant to ongoing philosophical discussions of personal identity, particularly by those influenced by neo-Lockean, memory-based criteria for personal identity. These focus on clinical phenomena that in certain respects parallel fictional and philosophical fantasies, such as Dr. Jekyll and Mr. Hyde, or Locke's own "day man" and "night man," in raising questions about the relationship between persons, minds, and bodies, as well as about the identity of persons over time. Similar questions are nascent in more recent discussions of enhancement technologies.

Split-Brain Cases. These are chiefly examples in which patients have undergone the surgical procedure of commissurotomy, which severs the corpus callosum that provides the primary neurological channel connecting the left and right hemispheres of the brain. Commissurotomy as a surgical technique was first performed on patients with severe forms of epilepsy featuring grand mal seizures in 1940. Split-brain cases were initially described by the Nobel Prize winning neuropsychologist Roger Sperry (1966, 1968a, b), following work that he had undertaken with the neurosurgeon James Bogen at the California Institute of Technology. Sperry's characterizations provoked much discussion in the philosophical literature on personal identity in the 1970s and 1980s (see Marks 1981; Dass 1995).

The initially surprising finding was that patients who had undergone commissurotomy manifested recognitional behaviors that differed markedly, depending on how those behaviors were elicited. For example, when presented with a visual stimulus shown tachiscopically for 150–200 ms in the left of the visual field, and asked both if they had seen anything and to describe what they had seen, patients showed no awareness of these stimuli; when probed to draw or guess at what was presented, however, such patients performed significantly better than chance. The explanation for this perhaps innocuous-sounding discrepancy is that the left visual field, which is processed in the right hemisphere, has a functional specialization for imagery and nonverbal processing. Since the primary signaling channel between the hemispheres is absent following commissurotomy, there is information available to the right hemisphere that is isolated from the left hemisphere, which has a functional specification for language and categorization. Hence, a probe that draws on the left hemisphere, which lacks information about the stimulus, will elicit non-recognitional behaviors; a probe that draws on the right hemisphere, which does possess that information, elicits recognitional behaviors. Further discrepancies found between how patients reported information acquired through tactile and visual modalities could be explained in a similar manner.

Sperry claimed that results such as these suggested that "the surgery [commissurotomy] has left these people with two separate minds, that is, two separate spheres of consciousness" (1966, p. 299). Reports of these findings of split-brain cases were thus sometimes interpreted as cases in which there were two persons in one body, with the Canadian philosopher Roland Puccetti arguing further that this is the proper way to think about persons and their bodies more generally (Puccetti 1973a, b, 1981).

Psychiatric Disorders Involving the Disorder of the Self. Perhaps the most prominent psychiatric disorders involving the self are dissociative disorders, including multiple personality disorder, which was recognized in the Diagnostic and Statistical Manual of Mental Disorders (DSM) in both its second and third editions, published, respectively, in 1968 and 1980. This medical conception of the nature of the disorder, which built on the popular idea that a given human body may well possess more than one personality and that these personalities can govern the behavior of that body in very different ways, comported with the kind of speculation fueled by the work on "split-brain patients" in that it seemed also to lend itself to a philosophical gloss of there being at least "two persons in one body," each causally responsible for directing the behavior of that body at different times (cf. Braude 1991). The substantial

reconceptualization of MPD as "dissociative identity disorder" in DSM-IV (1994) as requiring "the presence of two or more distinct identities or personality states" that alternately control the individual's behavior, and that manifest relatively cohesive narrative memories that are isolated from one another, in effect suggests that disintegration of the self, rather than its multiplication, is at the heart of the condition. Perhaps "multiples" have less than, rather than more than, one self (see Hacking 1995).

Memory Loss Over Time. The third cluster of empirical phenomena that philosophers thinking about personal identity in the neo-Lockean tradition have appealed to concern cases of extreme, even if gradual, memory loss over time, such as one finds amongst Alzheimer's patients and others suffering from age-related forms of dementia. Central to such afflictions is the loss or severe diminution of memory, not simply narrative memory of one's past but of the ability to recognize one's family or close friends and one's even quite recent interactions with them, as well as the abilities to remember and act on one's own plans and expressed desires, and procedural memory for knowing how to perform actions, such as driving a car or riding a bicycle. As such abilities decline, so too does one's capacity for a cohesive mental life, calling in to question the relationship between one's self at distinct times, such as the past and present or the present and future (de Grazia 2005, Chap. 5).

Enhancement Technologies. More recently, some discussions of personal identity have shown sensitivity to developments in the clinical sciences concerned with cognition and the mind that focus not so much on traditional pathologies but on enhancement technologies. For example, Carl Elliott (2003) has discussed the variety of ways in which technologies – ranging from accent reduction training and other forms of voice modification through to the psychopharmacological mood adjustments induced by drugs such as Prozac that lead some users to describe themselves as feeling "better than well" or as finally being able to "be themselves" – have been developed and used to influence one's sense of narrative identity over time. Some such technologies, such as cochlear implants and prosthetic limbs, literally augment the brain and body of a person in ways that either restore missing or lost capacities or enhance such capacities beyond those possessed by the fictional normal persons. Although these discussions have been typically cast in terms of the cultural and scientific significance that such technologies have for conceptions of the self, public policy, and individual lifestyle, they remain relatively undigested in the literature on personal identity. Likewise, consider the more science fictional projections of transhumanists who are focused on the possibility of substantial life span extensions that involve technologies allowing for the downloading of human minds into new bodies or even nonbiological forms of instantiation (Kurzweil 2005; Agar 2010). Both the presumptions of and implications for such possibilities vis-à-vis personal identity have received some recent discussion (Schneider 2009).

Extended Cognition and Extended Minds

The empirical work drawn on in discussions of personal identity recounted above has tended to reflect the predominance of psychological and more particularly

memory-based views of personal identity. Such views have taken the brain and neural activity to be distinctive, vis-à-vis personal identity, from merely bodily activity. In this section we turn to views of cognition, including of memory, that question whether neural activity itself is sufficient for cognitive processing of particular kinds or even for having a mind. According to proponents of the extended mind thesis (Clark and Chalmers 1998), or the hypothesis of extended cognition (sensu Rupert 2009), the answer to these questions is "no."

The extended mind thesis holds, perhaps counterintuitively, that cognition does not take place exclusively in the head of the cognizer. As such, it is a form of externalism about the mind or cognition that developed in the 1990s as part of a longer dialectic between individualists (Fodor 1987; Segal 1989; Egan 1991) and their externalist critics (Burge 1979; Shapiro 1993; Wilson 1994). In contrast to the debate between individualists and externalist to that point, which had focused on the notion of mental content or representation, proponents of the extended mind argued that minds or cognitive systems themselves were not fully located within the bodily envelope of the individual (Wilson 1995; Clark and Chalmers 1998). On this view, features of, or structures in, an organism's environment could in principle be, and sometimes in practice were, physical constituents of that organism's cognitive systems. Such cognitive systems are extended in that they do not begin and end at the skull or even body of the individual cognizer. The extended mind thesis can be readily motivated theoretically, as well as by reflection on everyday ways in which we rely on and even come to incorporate parts of our artifactual environment into our cognitive activities.

Theoretically, the possibility of extended cognition follows from functionalism in the philosophy of mind, where what matters for cognition is not the what or the where but the how of cognition. For at least a sophisticated form of functionalism, cognitive processing is, in essence, a matter of a certain kind of structural and dynamic functional organization. Given the commitment to materialism shared by most functionalists, functional organization is physically realized and so physically located. But what does the realizing, and just where that matter is located, is of secondary importance. Networks of neurons organized in certain ways can realize particular cognitive systems, but so too might silicon chips so organized. And the physical stuff realizing such networks is often located inside a skull, but it may also be distributed between head and world. Thus, certain kinds of parity considerations lie at the theoretical heart of the idea of extended cognition, ones that appeal to functionalist commitments that we view as running deep in the cognitive sciences (Clark and Chalmers 1998; Wheeler 2010; Wilson in press).

In terms of reflection on everyday cognitive activities, consider our systematic reliance on pen-and-paper calculation in order to solve even minimally complicated multiplication problems. Here we store intermediate solutions on the paper, using perception and action to mediate information flow between the symbols stored in our heads and those stored on the paper. The cognitive process of solving a multiplication problem, in this case, involves integrated information processing both inside and outside of the person's body. Moreover, as the workload involved in many cognitive tasks increases – more information to store and track, higher

attentional demands, more levels to decision-making – the corresponding cognitive processing comes to systematically depend on the smooth integration of in-the-head cognition with cognitive tools and structures outside of the head. Proponents of extended cognition take such examples of cognitive offloading to point to how extended cognitive systems have been shaped evolutionarily, developmentally, and culturally for everyday cognitive tasks (Clark 2008; Wheeler 2005; Wilson and Clark 2009). Cognitive scientists adopting a "situated cognition" perspective on a variety of topics, such as problem solving (Kirsh 2009), learning (Sawyer and Greeno 2009), and rational decision-making (Brighton and Todd 2009), continue to explore systematically the role that such offloading plays in everyday cognition.

A more precise statement about extended cognition that concerns particular cognitive activities and that makes explicit the idea of an extended cognitive system summarizes this overview of the extended mind thesis:

> A cognitive activity is extended just if it is generated or sustained by the activity of one or more extended cognitive systems.
> A cognitive system is extended just if it contains, as physical constituents, one or more processing resources that are not contained inside the head or body of that individual.

Multiplication performed by a person using pen and paper involves extended cognition, provided that (a) the pen and paper function as processing resources that are (b) not contained inside the head or body of that person, and (c) are physical constituents of a cognitive system which (d) generates or sustains that activity. Those resistant to the idea of extended cognition and the extended mind can be viewed as rejecting one or more of these provisos, most commonly (a) or (c) (Adams and Aizawa 2008; Rupert 2009).

Although the extended mind thesis was originally articulated as a merely possible alternative to the view that cognition takes place entirely in the head, the thesis has come increasingly to be defended as a plausible view of much actual cognition. As such, it has appealed to ongoing work in the cognitive sciences in support of this claim (Wilson 2004; Clark 2008; Wilson and Clark 2009; Wilson in press), including the use of gesture for linguistic communication (Clark 2008), action-guided views of perception (Wilson 2010), and memory (Wilson 2005). Given that memory has played a prominent role in discussions of both the extended mind and personal identity, we make that our focus below.

External memory storage for problem solving, planning, and decision-making features in both the multiplication example we have discussed as well as Clark and Chalmer's (1998) classic Otto-Inga thought experiment in which one person, Otto, compensatingly comes to rely on and utilize a notepad as effectively as another person (Inga) uses internal memory storage for finding one's way to a particular location in a city. The kind of parity considerations in play here can be used to motivate a broader rethinking of the kind of memory central to personal identity.

While there are many ways in which memory has been conceptualized – short term vs long term (Atkinson and Shiffrin 1968), episodic vs semantic (Tulving 1972, 1983, 2010), procedural vs declarative (Graf and Schacter 1985;

Schacter and Tulving 1994; Schacter 2010), and iconic vs linguistic (Sperling 1960; Neisser 1967) – as we have seen, it is narrative or autobiographical memory that is most directly relevant to discussions of personal identity. The sense of having a continued psychological existence over time, such that one can remember oneself having done certain things in the past, matters to us and is what allows us to guide our current actions and plan our futures in light of who we are.

Such narrative or autobiographical memory, particularly in its individualistic guise, might be thought to fall under the broad umbrella of declarative (vs procedural) memory since it is, more specifically, a type of episodic memory involving autonoetic (or self-knowing) awareness (Tulving 2010). Autonoetic recollection of an event is essentially a reexperiencing of a past experience, making episodic memory a clear example of tracking a self – one's own self – through time and thus well suited for tracking personhood over time.

Given the extended mind thesis, however, narrative memory need not be bound exclusively to individualistic recollection but can come to incorporate the world beyond the individual in a variety of ways. One such way involves cognitive offloading. In fact, Daniel Dennett's "Making Things to Think With" illustrates our habit of offloading cognitive tasks into the environment with the example of elderly people who are incapable of recalling simple daily routines and suffer from other memory-related deficiencies once they are housed in institutions such as nursing homes (1996, pp. 134–139). Many such signs of dementia are less pronounced or disappear altogether once people are returned to their own homes where they have offloaded many of their daily routine schedules (such as taking their medications) on items or places that remind them of what they have to do, how they ought to do it, and other kinds of pertinent information.

Even though narrative memory has typically been conceptualized individualistically, as with other forms of extended memory, it can come to integratively rely on aspects of familiar environments, as in Dennett's example of cognitive offloading (cf. also Wilson 2004, pp. 189–198). But extended narrative memory also departs from individualism in another way: it can be shared and co-constructed by two or more individuals (Wilson 2004, pp. 191, 207–211; cf. Barnier et al. 2008).

This second dimension to extended narrative memory might be thought to call into question a putatively clear-cut distinction between autobiographical and collective memory. Collective memory has received much discussion over the past decade or so in the humanities and social sciences, especially in Holocaust and trauma studies (see, e.g., Olick, 2011; see also Wilson 2005, Theiner 2008, 2013). Collective memory is often commemorative of significant past events, ritualistic, and political in nature. For example, we collectively remember atrocities on the calendar date on which they were committed or engage in joint actions that express our political affinity and sympathy with (other) victims of a crime or natural disaster.

We think that we can maintain a version of the distinction between narrative and collective memory by thinking of the sharing of one's narrative memories in the same way that we can think about the offloading of those memories. Integrating things in one's immediate environment to form an extended memory system is a

form of extended cognition utilized by people with Alzheimer's disease and other neurodegenerative conditions affecting memory. Here it is the individual who remembers, but the activity of remembering is extended, being distributed between that individual and things in her environment. Likewise, when one's narrative memories involve a co-participant, it is still one's self who remembers, even if the activity of remembering is socially extended, being distributed between the individual and her co-rememberer. What one needs, in both cases, is some kind of asymmetry between the person whose autobiography is being actively constructed and the things or other persons involved in that construction (for one account, in terms of the notion of locus of control, see Wilson 2004, pp. 184–187, 197–198).

In contrast to such cases of extended narrative memory, in cases of collective memory it is some kind of collective or group that remembers, distributing the task of remembering between different individuals within a group in ways that make it implausible to identify any one of them as "the" person who remembers. In fact, what is remembered in collective memory is not autobiographical, even if it involves things that have happened to particular individuals (or even just one individual). It is remembering that is (typically) episodic but not autobiographical.

The relationships between extended and collective memory require exploration beyond our necessarily brief comments here. One general claim that has been made about "group minds" that may prove relevant here is that many putative examples of collective cognition are more plausibly viewed as cases in which the extended cognition of the individual involves a social environment involving other people. This social manifestation thesis – "the idea that individuals engage in some forms of cognition only insofar as they constitute part of a social group" (Wilson 2005, p. 229) – can be applied to memory and viewed as offering both a challenge to proponents of group minds and potentially, at least, an expanded role for the extended mind thesis (see also Wilson 2004, Chaps. 11–12; Barnier et al. 2008). That expanded role contains implications for personal identity.

Extended Personal Identity

An externalist neo-Lockean account of identity is not as puzzling as it may initially sound, especially given that the psychological account appeals so directly to narrative memory. As Alasdair MacIntyre (1984) has observed, people are essentially storytelling animals. The narrative tools we employ to make sense of our identities arise in cultural, historical, and institutional settings. When we take memory seriously in the context of personal identity, it becomes clear that individual identities, just like individual memories, are realized within the context of collective narratives. Individual memories may well serve as the vehicles for individual identities. But such memories are influenced by collective narratives, thus making individual identities heavily reliant on the collective or social contexts within which individuals exist. An appreciation of this relationship between individual rememberers and the collective narratives in which they are immersed

should not only compel us to rethink our understanding of memory, but should also inform our conception of personhood.

The intimate connection between individual and collective remembering has been noted by researchers studying memory since the 1930s. For example, F. C. Bartlett (1932) argued that interests, in the broad sense, taken to mean the development of a person's mental life, are responsible for what a person remembers. Moreover, Bartlett argued that interests themselves have a social origin (p. 256) in customs, institutions, and traditions, which constitute a lasting social schema (p. 264). Rephrased in the language of the social manifestation thesis, Bartlett's argument is as follows: remembering is private and subjective insofar as the individual doing the remembering does so privately. However, all remembering is made possible and is shaped by the social constructions and contexts in which the remembering occurs.

This kind of relationship between individual narratives and collective remembering suggests that the extended mind thesis may be well positioned to augment traditional neo-Lockean views of personal identity. Suppose that the cognitive capacities involved in remembering are not intrinsic to the individual whose identity is being tracked, but are socially manifested capacities. This would imply that a person's identity has a wide realization. Tracking a person's identity over time, on this view, would involve many minds, including the mind of the individual who is tracked. But since "the characterization of wide realizations preserves the idea that properties with such realizations are still properties of individual subjects" (Wilson 2004, p. 141), this externalist view of personal identity does not entail that the individuals who are persons are themselves "wide" or "extended" selves.

Combining a psychological account of personal identity with the extended mind thesis in this way provides one with the resources to solve some of the problems facing standard neo-Lockean views, problems that stem from the individualistic ratio-centrism of such views that we identified earlier. It does so by recognizing narrative-based criteria for personhood that are based on more than just the intrinsic cognitive capacities underpinning the remembering of the normally abled.

The case of patient HM, who suffered from memory loss following bilateral medial temporal lobe resection (Scoville and Milner 1957), serves as an example of an individual whose diachronic identity has been more dramatically socially realized. HM lost the ability to consolidate new information into long-term episodic memories, thereby losing the ability to autonoetically track his own identity over time. An extended account of identity enables a genuine maintenance of personal identity on behalf of individuals who, like HM, are incapable of tracking their own personhood through time.

Recognizing a socially extended realization base for personal identity dovetails with some recent work of Hilde Lindemann on the role that others play in "holding us" – all of us – in our identities. Lindemann (2010) argues that a person's identity is both shaped and preserved by others via the complex interactions between, and varied intertwining narratives remembered and transmitted within, families and other groups. Echoing Dennett on the environmental offloading of cognitive tasks

by proposing that places as well as people can hold individuals in their identities, Lindemann writes:

> It's not just other people who hold us in our identities. Familiar places and things, beloved objects, pets, cherished rituals, one's own bed or favorite shirt, can and do help us to maintain our sense of self. And it is no accident that much of this kind of holding goes on in the place where our families are: at home. (Lindemann 2010, pp. 162–163)

Thus, externalism does not merely change the way we understand the mind; it also affects how we define and track personhood. Selves are a product of both individual and communal processes, and thus personhood should not be defined in solely individualistic terms. To think of personhood as purely individualistic and private is as much a mistake as thinking of memory in such terms.

Maurice Halbwachs once mused that in order to experience private remembering that is minimally influenced by social contexts, we should look to our dreams, which "are composed of fragments of memory too mutilated and mixed up with others to allow us to recognize them" (1941, p. 41). Persons, whose identity is strongly tied to memory, must have widely realized identities that emerge in a social context. They are formed by, held in, and tracked via the memories of others, which themselves are shaped by the collective memories of the various social groups to which these individuals belong.

Concluding Thoughts

The extended mind thesis makes the claim that minds extend beyond the skull. Analogously, the externalist account of personhood might be taken to make the claim that persons themselves are extended in just this way. Although some proponents of the extended mind thesis may indeed be taken to advocate or welcome such a claim (see Clark 2001, 2003; cf. Clark and Chalmers 1998), we have sketched a somewhat less radical view. On our view, what is extended or widely realized is the identity of persons while persons themselves, as the subjects of identity over time, are not extended or wide. An individual's personal identity is, to be sure, an important property of that individual, and it is not determined solely by properties or capacities intrinsic to the body of that individual. But like other properties that individuals have that require external resources to be realized, this extended property is still a property of a spatiotemporally bounded and located individual.

All persons can and do rely on others to maintain a cohesive narrative identity. Individuals with cognitive limitations that create difficulties for their tracking their own identities, thus magnifying the problems that we all face in preserving a coherent conception of ourselves, may depend on others more deeply to maintain such cohesive narratives. This provides one way in which an externalist view of narrative identity allows individuals who have traditionally been viewed as falling below the status of personhood – namely, those with severe or increasing cognitive

disabilities and limitations – to manifest personhood. And it does so without viewing their status as persons as different in kind from that of others. Like the regularly cognitively endowed, their personal identities are socially manifested properties, albeit ones that are more deeply reliant on their social context.

Consider persons who slip gradually, over time, into ongoing states of dementia. On an externalist account of personhood, such persons need not forfeit their identities as their minds and memories deteriorate. This is because even though they gradually lose their capacity for individual memory, their identities are realized in the collective remembering of others. Because the externalist account of personhood does not share in the ratio-centrism that individualistic variants of the psychological approach manifest, it has a greater potential to recognize full personhood in such cases.

Embracing the idea of extended narrative memory is one way to broaden neo-Lockean views in ways that make them apt to be more inclusive about persons. But the shift from an individualistic to an extended mind view also serves to pry neo-Lockean views from their traditional ratio-centrism in other ways as well. One reason why ratio-centrism is so deeply embedded in the psychological account is that most variants of the neo-Lockean approach focus solely on memory as a criterion for diachronic identity. Persons, and more specifically, personalities, however, are constituted by more than merely episodic memories. Robert Nozick (1981), for example, states that "[f]or a life to have meaning, it must connect with other things. . .or values beyond itself" (Nozick 1981, p. 594). Some examples of such meaningful and valuable external relations are relationships with other people, continuing and advancing a tradition, children and families, etc. What all such externally valuable relations have in common is that they are saturated with emotive states. Emotions not only color memories but make some more significant than others. What we remember about ourselves or others, the very narratives that constitute identity, are shaped and made more or less meaningful and thus significant by our affective states during memory formation and recollection.

Emotions, like memories and identities, should be understood externally. As Sue Campbell has pointed out, affective states must be expressible in order to be individuated (1997, p. 66). Campbell's view that what we feel is largely determined by what we express leads to the worry that some individuals can be quite vulnerable to being controlled by others. Campbell explains: "One of the most obvious ways in which our feelings are controlled through their expression is by the power of interpreters to view the occasions of our lives and respond to our expressive acts" (1997, p. 135). Such control over affective states can be easily carried over to controlling large portions of someone's narrative and thereby shaping and constructing an inauthentic identity (see Levy 2007a, b).

Issues of authenticity also emerge in the context of extended identity. Levy argues that an acceptance of the extended mind thesis voids the distinction between neurological interventions "by way of psychopharmaceuticals, transcranial magnetic stimulation, or direct brain stimulation" (2007a, p. 7) and more traditional methods of altering mental states, such as using psychological practices like talk therapy or even enhancing one's nutrition or education (2007a, p. 9). This dissolves

Carl Elliott's (1998, 2003) worry "that if antidepressant use alters my personality traits, it [my personality] is inauthentic, inasmuch as these personality traits cannot be a genuine reflection of who I am" (Levy 2007a, p. 7) since, according to the extended mind thesis, both internal and external interventions are regular occurrences, which contribute to what we consider to be our authentic selves.

The question of authenticity, however, crops up again in the context of an externalist account of *personal identity*, since other people have the power to interpret narratives that constitute a person's identity because "identity maintenance also involves weeding out the stories that no longer fit and constructing new ones that do" (Lindemann 2010, p. 163). Not all such weeding and rewriting of narratives is going to be authentic since facts can be carelessly, as well as purposefully, misinterpreted by others. The worry Campbell raises regarding the power interpreters have over the narratives they interpret is recognized by Lindemann, who recognizes that it is certainly possible to hold someone's identity wrongly or at least clumsily. Narratives must be truthful if they are to genuinely track someone's identity, meaning that the backward-looking narratives that constitute a person's identity must pick out something about that individual that is saliently true. For example, "[i]f you never went to med school, aren't licensed to practice, and don't see patients, then you aren't a doctor, and neither I, nor your doting mother, nor God himself can hold you in that identity" (Lindemann 2010, p. 164). Since inauthentic narratives fail to track individuals genuinely, in effect they mutilate a person's identity and thereby devalue the personhood of the individual.

The externalist account of personal identity thus reveals a fragile side of personhood that remains hidden in individualistic variants of the neo-Lockean approach. Understanding the sensitivity of narratives to interpretative interventions deepens our understanding of what it means to treat people and their identities authentically. Whereas traditionally, personal identity was almost exclusively tied to individualistic episodic memory, the externalist account of personal identity sees narrative integrity, in both its individual as well as collective manifestations, as an essential constituent of diachronic identity. Consequently, extended personal identity not only restores the narrative identities of individuals with severe cognitive disabilities, but also generates a moral imperative toward truthfulness in treating, transmitting, interpreting, and holding of person-tracking narratives.

Finally, extended personal identity acknowledges a variety of people. That is, to the question "what sorts of people are there?," the extended neo-Lockean view points to many more kinds of people than do more traditional accounts. On the extended account, individuals traditionally denied one of the important perks of personhood, namely, *personal identity*, are recognized as having it, despite having cognitive capacities that depart from those typical or normal for (other) persons. Moreover, the extended account of personal identity morally obliges us to protect the authenticity of personal narratives not merely via acknowledgment, but actively (via actual conduct) since we are directly and genuinely responsible for them.

Mind, Brain, and Law: Issues at the Intersection of Neuroscience, Personal Identity, and the Legal System

Abstract

The objective of this chapter is to consider how emerging neuroscience might affect the way that the concept of personal identity is understood and used in the law. This topic is explored using two well-established theoretical approaches to the concept of personal identity. One approach considers the physical and/or psychological criteria for establishing the boundaries of one single personal identity at a given time (synchronic numerical personal identity) or the continuity of one personal identity over time (diachronic numerical personal identity). Another approach conceives of personal identity as "narrative identity" or the self-conception that a person creates from the sum of their experiences, values, and psychological attributes.

A concern with what makes two apparent beings the same person at one point in time (synchronic identity) brings into focus questions about how the law should respond to cases of accused persons with dissociative identity disorder. Neuroimaging and psychological research into dissociative identity disorder may one day alter the conceptualization of this disorder in ways that may affect the legal response to determining criminal responsibility in such cases. Meanwhile, a concern with changes in the "self" brings into focus a range of legal issues posed by emerging neurological interventions. The chapter offers three illustrative examples drawn from criminal and civil law: (1) What are the limits on legally coerced consent to "self"-changing rehabilitative brain interventions in the criminal context? (2) Should there be an expanded risk disclosure discussion during the informed consent process for medical treatment that may alter the "self"? (3) Who might be legally responsible for illegal behavior committed following "self"-changing brain interventions?

Introduction

The objective of this chapter is to consider how emerging neuroscience might affect the way that the concept of personal identity is understood and used in the law.[1] The law does not employ a single unified concept or theory of personal identity. Instead, personal identity and related concepts such as personhood are used in a variety of legal contexts and for a variety of purposes such as the recognition of legal rights and duties, the assignment of legal liability, and the creation of property rights (see, e.g., Radin 1982, discussing the personhood theory of property rights).

This chapter links the law to two well-established theoretical approaches to personal identity. First, the question of numerical personal identity, or the conditions that make one person the same person at a different time (diachronic identity) or that establish that two beings are the same person at one point in time (synchronic identity), is a familiar topic in philosophy (Olson 2003; DeGrazia 2005). Since only the person who committed an alleged crime may be held criminally responsible for it, the appropriate criterion for establishing that an accused is the person who committed an allegedly criminal act is important. In most cases, this is a practical problem flowing from the frailties of the identification evidence available, rather than a philosophical problem of numerical identity. However, as discussed below, the example of dissociative identity disorder has forced courts to grapple with the possibility that multiple legally distinct identities might exist within one body. Continuing neuroscientific and psychological research into this disorder may come to influence judicial reasoning in these cases.

[1]The legal principles and cases used in this chapter to illustrate the intersection of concepts of personal identity, neuroscientific knowledge, and the law are predominantly Canadian.Similar issues will confront other legal jurisdictions, where the reasoning and principles may be different.

The second theoretical approach reflected in this chapter is that of "narrative identity." This approach is concerned with a person's answer to the question "who am I?" This is a question that could produce many answers, and there are many elements that are conceivably relevant to the formation of one's self-conception (Merkel et al. 2007). Schermer (2011) describes narrative identity as a "person's self-conception, his biography, values, and roles as well as his psychological characteristics and style." Thus, one's behavior (both past actions and plans for the future), personality, values, and social roles and relationships are knitted together into an intelligible account of oneself over time that constitutes one's narrative identity. Theories of narrative identity generally recognize that the story of the self emerges within a social context such that "we are never more (and sometimes less) than the co-authors of our own narratives" (Schechtman 2011, citing MacIntyre 1984; Baylis 2011).

The breadth of inquiry permitted by narrative theories of personal identity is useful for this chapter as it allows for a focus on a wider range of legal preoccupations that might ultimately be affected by neuroscience. Furthermore, the neuroethics literature frequently raises issues related to the impact on self-conception of neuroscience, neuroessentialism, and emerging methods of manipulating brain function. This chapter thus links to that literature in identifying legal dimensions of the topics of interest to neuroethicists.

Accordingly, the second part of this chapter addresses three particular instances in which the law, neuroscience, and narrative identity come together. Each of these instances involves a change in mental attributes (cognitive functions, personality traits) that are a fundamental part of the answer to the question "who am I," and in each case, a legal question is raised. The first question is how we should distinguish between those brain interventions that a convicted criminal could be legally coerced into accepting in order to avoid imprisonment and those that could not legitimately be offered in this way. The second issue relates to the law of informed consent to medical treatment and asks whether the scope of risk disclosure should be broadened for brain interventions to include a range of social and legal consequences of treatment. The third issue relates to who might be responsible for harm caused by a patient who has undergone a brain intervention such as deep brain stimulation. Together, these three topics are meant to illustrate the ways in which neuroscience, particularly interventions that affect the "self," poses challenges for the law.

Personal Identity and Responsibility: "Who Did It?"

From the legal perspective, personal identity is of central importance in ascertaining who is to be held responsible for a crime. Put simply, the objective is to determine "who did it?" Instances of wrongful conviction – where the person convicted and punished is later found not to have been the person who committed the crime – are recognized as miscarriages of justice. The issue of numerical

identity – are "this and that…one thing, rather than two" (Olson 2003) – is a familiar topic in the philosophy of personal identity. One may ask this question as an issue of persistence over time, in which case the question is under what conditions can we say that a person at one time is the same as one that exists at another time? Theories of personal identity tend to emphasize the importance of some degree of physical continuity and/or psychological continuity as the criteria that establish personal identity over time (Olson 2003). One may also ask the question of synchronic numerical identity, as in the case of dissociative identity disorder, in which case the problem is to understand what establishes the boundaries of a distinct personal identity at one point in time.

In criminal cases, a perpetrator may be identified on the basis of physical attributes (e.g., through eyewitness reports, fingerprints, or DNA), as well as using evidence such as opportunity or motive. Since a satisfactory level of psychological and physical continuity over time is the norm for human beings, the law rarely has to take a position on which of the two – mental attributes or physical attributes – establishes that the accused is actually the person who committed the crime. The familiar philosophical thought experiment of tracking personal identity where the cerebrum is removed from one person and transplanted to another is not the type of complication that the law must address. Rather, concerns related to identity flow more from the practical problem of the quality of the evidence of physical identity, as wrongful convictions due to the frailty of eyewitness evidence demonstrate.

However, in some cases, the law is forced to grapple with uncertainties about whether the accused is the "same person" who committed the alleged crime, notwithstanding that personal identity seems to have been established on a physical basis. The issue of dissociative identity disorder has arisen in a range of cases where perplexed courts have had to decide whether to believe the claim of the "host" identity that an "alter" identity committed the allegedly criminal act. Where they do believe it, they must then decide whose mental state and capacity must be examined to determine the existence of mens rea, and how one can punish just one identity without simultaneously punishing "innocent" identities.

Dissociative identity disorder is not the only context in which dissociation must be addressed by the courts. The law also addresses criminal acts committed during a state of dissociation (sometimes called "automatism" in legal terminology). In these cases, the law typically continues to assume that the dissociated person is still the *same* person while committing the offence, and instead approaches the matter as a question of whether the requisite mental state for responsibility was present at the time. Isolated incidents where there is no underlying mental disorder that suggests a risk of recurrence may be treated as aberrations leading to an acquittal (e.g., *R. v. Bohak* 2004). Most often, however, courts will find the accused not criminally responsible due to mental disorder (formerly, the defense of insanity) (*R. v. Luedecke* 2008; *R. v. Stone* 1999).

The more extreme case of dissociative identity disorder, in which well-developed alternate personalities are said to inhabit one physical person, comes closer to obliging a court to grapple with the proper criterion for personal identity.

As one Canadian judge put it when sentencing a man who had pleaded guilty, but whose crime seemed to have been committed by an alternate personality,

> The problem is that the "person" before me is not the "person" who committed the crime nor is it the "person" who will serve the sentence. Physically, the appropriate individual is present in Court, but the guiding, controlling force which perpetrated the crimes is deep within the physical body of Stephen and waits there, unaffected by any conventional sentence I might impose. . .Though the current state of the law requires me to sentence the physical being who committed the offenses, I am permitted to take into account as I craft my sentence that, in essence, another being orchestrated the events. (*R. v. O'Flaherty* [1992] A.J. No. 96)

Courts have responded to claims of dissociative identity disorder in various ways, sometimes refusing to believe the claims. Where the claims are believed, some courts focus on the state of mind of the identity in charge at the time of the allegedly criminal act and hold the accused guilty if that identity had the requisite mens rea. Others focus on the mental state of the "host" or dominant identity, with attention to whether the "host" can be said to have been incapable due to mental disorder (Crego 2000). Although fairly rare, cases in which dissociative identity disorder are raised continue to surface (e.g., *State v. Dumas* 2012).

Dissociative identity disorder remains a contested and poorly understood condition (Boysen and Van Bergen 2013; Boysen 2011). Psychological and neuroscientific research is proceeding and may eventually affect legal responses to the disorder. For example, Reinders (2008) speculates that structural and functional neuroimaging may one day help in distinguishing between real and feigned cases of dissociative identity disorder, although she cautions that existing research is inadequate for forensic use. However, even if such evidence confirms that a case of dissociative identity disorder is genuine rather than feigned, the law must still address the problem of whether the accused person is to be considered legally responsible. The legal threshold for responsibility looks not at medical diagnosis but at the capacity to understand the nature and quality of the acts in question and to know that they are wrong. As a result, the problem of determining actual capacity at the time of the crime will remain even if neuroimaging one day is able to support a diagnosis of dissociative identity disorder.

Another possible effect of ongoing research is suggested by studies of the extent to which alternate identities are truly separate. If it is shown that there is actually overlap in mental functions between identities, the argument for identity based on distinct psychological attributes (which is what remains to establish separate identities given that they share the same body) may be weakened. In other words, the situation begins to look more like one of a single disordered identity than of multiple distinct identities within one body, each of which can be assessed independently for mental competence and criminal responsibility.

One line of research focuses on the extent to which one identity remembers words presented to another despite claimed inter-identity amnesia. Huntjens et al. (2007) conclude that there is evidence of the transfer of information between identities in dissociative identity disorder and that "[t]hese findings strikingly contrast with the patient's subjective reports of amnesia for the task performed

and material learned by the learning identity." They further suggest that studies of this type may be important for the conceptualization of dissociative identity disorder in the future, with the disorder being a disturbance in "metamemory functioning" or knowledge, beliefs, and feelings about memory, rather than an actual fragmentation of memory. Evidence of this type might encourage the law to make a global assessment of an accused person's mental state, rather than, for example, focusing on the competence of the identity "in control" at the time of the alleged crime.

Brain Interventions that Affect Narrative Identity: "Who Am I?"

Discussions of personal identity often arise in neuroethics in relation to interventions in the brain that may affect mental attributes important to the self, including cognitive functions and personality attributes. Two key themes are the evaluation of the change in the self (i.e., on what basis might we judge a change to be good or bad) and autonomy in relation to a change in the self (i.e., what are the conditions for an autonomous decision to change the self, and when is it acceptable to coerce a change in the self). A third issue, which arises less frequently in neuroethics, is the question of responsibility for behavior clearly associated with a major change in personality following a brain intervention.

This section selects three legal questions relating to brain interventions that may alter the mental functions and characteristics important to personal identity. The first issue emerges from criminal and human rights law and has to do with the limits on legally coerced consent to rehabilitative treatment in the criminal context. The second has to do with the civil legal question of the scope of risk disclosure required for informed consent to medical treatment in the context of emerging brain interventions where a range of nonmedical (i.e., social or legal) consequences may flow from treatment. Finally, the third question is who might be responsible for harm caused by a patient who has undergone a brain intervention such as deep brain stimulation. Together, these three topics are meant to illustrate the ways in which neuroscience, particularly interventions that affect the "self," poses challenges for the law.

What are the Limits on Legally Coerced Consent to Identity-Changing Brain Interventions in Criminal Offenders?

The law pressures convicted criminal offenders to accept treatment at several stages of an offender's transit through the criminal justice system. For example, acceptance of treatment allows some offenders to avoid incarceration through diversion to specialized drug treatment courts (e.g., the Toronto Drug Treatment Court). Cooperation with treatment is also considered at sentencing and in parole decision-making. Sentencing judges tend to view acceptance of treatment favorably because it is thought to demonstrate better prospects for rehabilitation. Judges also sometimes

view offenders who accept treatment as showing remorse and taking responsibility for their crimes, both of which can be mitigating circumstances at sentencing. Acceptance of treatment is particularly important for serious repeat offenders who are at risk of indefinite preventive detention as "dangerous offenders" under the Canadian Criminal Code. Those whose riskiness is deemed to be controllable in the community (e.g., through medical treatment) may be released under long-term supervision orders following completion of their prison terms. A range of biological interventions that arguably change important aspects of personality and behavior are available, such as the widely used antiandrogen drug therapy ("chemical castration") for sex offenders (Grubin and Beech 2010; *Deacon* 2006).

As we accumulate more knowledge about neurobiological predispositions to criminal behavior and we develop a broader array of potential techniques to intervene in the brain, the issue of what types of treatments an offender can be legally coerced to accept rises in importance. The temporary resurgence of psychosurgery for drug addiction in China and Russia (Lu et al. 2009; Hall 2006; Stelten et al. 2008), as well as the possibilities of deep brain stimulation for addiction (Luigjes et al. 2012) and psychiatric indications, demonstrates the importance of this question.

The answer to the question of whether an offender may legitimately be asked to consent to a particular brain intervention in exchange for a legal advantage depends upon how one categorizes the offered alternative from the perspective of the philosophical justifications of punishment. From the retributivist perspective, punishment is the infliction of deserved harm on an offender (see, e.g., Honderich 2006, for a discussion of this proposition). The extent and type of harm is subject to the limits posed by the human right not to be subjected to "cruel and unusual punishment" (e.g., UN General Assembly, 1948, article 5; Canadian Charter of Rights and Freedoms 1982, Sect. 12). Various consequentialist justifications of punishment also exist, one of which is that punishment should incapacitate offenders in order to stop them from offending again. From this perspective, a biological intervention might be understood not as retributive harm but as a way to protect the public by moving the prison walls into the body – a kind of "somatic regulation" to replace supervision or incarceration (Vrecko 2010). This vision of criminal justice as "risk management" is concerned primarily with the effective protection of the public rather than with the well-being of the offender. Finally, a biological intervention may also be viewed as rehabilitative, the chief focus of which is to change the offender for his or her presumed benefit as well as the general social benefit. From a practical perspective, rehabilitation is likely the appropriate theoretical frame in which to consider a biological intervention since the participation of physicians is likely to be needed, and their ethical participation requires that the treatment benefit the offender. Although physicians practicing in the correctional context face challenging problems of dual loyalty and conflicting obligations to patients, other inmates, and society (Konrad and Völlm 2010, they are bound by ethical obligations of beneficence and non-maleficence to their patients (UN General Assembly 1982, Principle 3; Elger 2008). From this perspective, the limits on acceptable legally coerced biological interventions are set

by whether the offered intervention would produce a net benefit or harm to the offender – a calculation that is far from easy to make.

Whether a biological intervention actually inflicts net benefit or harm on the offender depends upon whether the personality and behavioral changes produced by the intervention (e.g., reducing the risk of future criminality) are more valuable to the offender than what has been lost as a result of the treatment. Whether this is the case is a complex question involving the effects of the intervention on physical and mental health and functioning, the effects on personal identity and autonomy, and the issue of whether there is inherent value in living in a way that conforms to social norms.

The safety and effects of biological interventions on physical health and mental functioning are evidently key components of assessing whether they are harmful or beneficial. This consideration is important given that there is a risk that societies may be tempted to use unproven treatments prematurely on offenders, who are an unpopular social group (Greely 2012).

The impact on personal identity of biological interventions designed to modify personality and behavior has also been raised as a key concern (Levy 2007; Shaw 2012; Vincent 2012). As narrative personal identity is always changing over a lifetime, it is implausible to suggest that change is in itself harmful. Instead, the evaluation must focus on a particular change in the context of a particular life. Relevant features of the change in personal identity that might affect the evaluation include its nature, magnitude, abruptness, permanence, and the degree to which the changed person is aware of and endorses the change as reflecting his or her authentic self. One concern with direct biological treatments such as interventions in the brain is that, unlike psychological "talk therapies" that rely at least in part on appeals to the rationality of the offender, biological interventions bypass the rational mind, working changes that the offender does not have the opportunity to resist or accept (Levy 2007; Shaw 2012; Bublitz and Merkel 2009; Vincent 2012; Bomann-Larsen 2011; Greely 2012). At the same time, some biological interventions may restore a capacity for self-awareness and critical reflection (Shaw 2012) or may create a subjective sense of feeling "more like oneself" (Bolt and Schermer 2009). In these cases, biological interventions are arguably beneficial rather than harmful to personal identity.

Autonomy is another value that may be affected by biological interventions that affect personality and behavior. Legal coercion to accept any type of treatment is an affront to autonomy. Medical ethics will need to determine whether the benefits of treatment outweigh the harm to autonomy of legally coerced consent. Thus, we leave behind the fact that any coerced treatment harms the autonomy of a competent person. Instead, we focus on the effect of biological interventions on autonomy in order to determine whether the interventions produce a net benefit or harm to the offender. Put another way, the primary question here is whether the offender's capacity for autonomous decision-making is increased or decreased as a result of the intervention. Frankfurt's (1971) distinction between higher- and lower-order desires is helpful here, as is the story of Odysseus and the Sirens. Sometimes an external means to control desires that are rejected by the self is a means to allow the

"real" self to flourish more fully. For example, some sex offenders report benefit from "no longer being preoccupied by sexual thoughts or dominated by sexual drive" so that they are able to participate in psychological treatment without distraction (Grubin and Beech 2010; BBC News 2009). When someone rejects an internal compulsion as a limit on their autonomy, a treatment that removes this impulse or enhances self-control may thus support their autonomy. Things are more complex when a person does not reject the lower-order desire at the outset but comes to reject it during treatment, so that the future person might be said to have increased autonomy while the autonomy of the present person is eroded.

As for the issue of whether there is inherent value in living in a way that conforms to social norms, there is undoubted value in avoiding social condemnation and punishment. We should not underestimate the value of avoiding "liberty-depriving 'total institutions' [such as prisons]. . .that sever ties to outside families, friends, jobs and communities" (Vrecko 2010). However, it is dangerous to assume that the ways of living promoted by social norms are inherently valuable or that criminalized ways of living are without value. The history of legally coerced "curative treatment" of homosexuality illustrates this point (King et al. 2004; Joyce 2009). Rehabilitation – imposed paternalistically for an offender's own good – has also been criticized as highly dangerous because it is sheltered by an ideology of humanity and beneficence that allows for just about anything to be done as long as experts regard it as beneficial to the offender (Lewis 1970). Furthermore, it is not always clear that the traits that biological interventions might target are always maladaptive (Hörstkotter et al. 2012).

In addition to these potential benefits and harms to the offender of legally coerced biological interventions, there are possible consequences for the broader society. Some have argued that rehabilitation that changes behavior and attitudes removes the very individuals best suited to argue for and represent dissident values, impeding possibly salutary evolution of morality and law (Durkheim 1982; Shaw 2012). Another possible harm to society is that we defuse one of the pressures for society to confront other criminogenic factors (e.g., social inequality) that may be challenging but important to address. Finally, legally coerced treatment creates a practical problem of equitable resource distribution. In the context of specialized courts such as drug treatment or mental health courts, it has been observed that the result of court-ordered treatment is that offenders jump the treatment queue ahead of non-offenders (Seddon 2007).

In summary, as knowledge accumulates in behavioral neuroscience and we develop new techniques of intervention in the brain to change behavior, we will need to confront the question of the proper boundaries on the coerced rehabilitative treatment of criminal offenders. Given the necessary participation of medical practitioners bound by medical ethical obligations, only treatments that are of net benefit to offenders can be coercively offered to them. Human rights guarantees, particularly the right to be free from cruel and unusual punishment, may also buttress this position. However, it is very difficult to determine benefit and harm in identity-altering treatments. One's identity changes over time, frequently in ways and as a result of experiences we have not chosen. Nonetheless, the idea of abrupt

treatment-driven changes that bypass the rational mind are disturbing to narrative identity – understood as a self-created story of one's life and an answer to the question "who am I?"

Should the Scope of Risk Disclosure Required for Informed Consent to Identity-Changing Brain Interventions be Broadened to Encompass Potential Legal Consequences?

Memory is one of the mental functions cited as fundamental to personal identity, and alteration in memories may thus be perceived as affecting identity. In recent years, an experimental treatment for posttraumatic stress disorder (PTSD) that has come to be known as "memory dampening" has attracted ethical attention. Among the concerns raised have been questions of its effects on personal identity and authenticity (see the summary in Chandler et al. submitted, 2013).

This novel pharmacological intervention is currently being explored in clinical trials and uses the beta-blocker, propranolol, to treat PTSD. Much of the ethical discussion of this treatment was based on the assumption that propranolol must be administered at or soon after the traumatic experience. This raised a concern, among other issues, about the unnecessary treatment of people who might not go on to develop PTSD which might expose them to side effects, waste health-care resources, and possibly deny them the opportunity for the positive psychological experience of "posttraumatic growth" (Warnick 2007; Calhoun and Tedeschi 2006). However, it now appears that propranolol may be administered after PTSD develops to disrupt the reconsolidation of traumatic memories (Brunet et al 2011, 2008; Menzies 2012, 2009). The evidence is mixed on whether this is an effective PTSD treatment, and also on the effects of the treatment on a patient's recall of factual details and emotional response to the traumatic memory. However, Menzies (2009) reports that his patients experienced "'fragmentation' of the memory and difficulty accessing it, minimal or absent distress when thinking about it and a feeling of emotional detachment, as if it were a normal non-traumatic memory or had happened to someone else." In a later larger study, Menzies (2012) reported that the treatment "diminished the integrity of these traumatic memories, resulting in a degree of amnesia for the traumatic event." Additional studies are required to understand the effects of propranolol on traumatic memories. However, if it is true that this treatment does produce fragmented memories, this might undermine a witness's ability to testify persuasively in court. Similarly, an oddly detached style of recounting a horrible experience might also undermine a witness's credibility. Since many traumatic experiences might give rise to criminal or civil legal proceedings, this treatment might thus have consequences for the patient's ability to testify effectively. Should this possible consequence of treatment form part of the risk disclosure required for a patient to give informed consent (Chandler et al. submitted, 2013)?

With narrow exceptions, medical law and ethics require that informed consent be given for medical treatment, either directly by the patient or by the patient's

substitute decision-maker if the patient is incompetent. Canadian law indicates that physicians must disclose the "material risks" of a proposed treatment, of alternative treatments, and of nontreatment. There is some vagueness in what counts as a material risk, although severity and likelihood are key criteria in determining whether a potential adverse outcome must be disclosed. Even if the ordinary person would not regard a given risk as material, it may need to be disclosed if a patient asks questions that put a physician on notice that a patient has particular sensitivities rendering the risk material to that patient (Picard and Robertson 2007). Sometimes a patient may describe a specific social factor (e.g., a concern with scarring flowing from the desire to conceal her contraceptive sterilization from her family, *Videto v. Kennedy* 1981) that makes her unusually sensitive to particular medical risks. Note, however, that the focus is still on identifying which medical risks must be disclosed, rather than on identifying and disclosing the range of indirect social consequences that must also be identified as risks of treatment.

Where standard medical treatments are at issue, the law of informed consent typically focuses on the obligation to disclose information about the direct medical effects of treatment (rather than their indirect social, economic, or legal significance) and, to some extent, also focuses on the obligation to disclose information about the physician (Picard and Robertson 2007; Borden Ladner Gervais 2000; Berg et al. 2001). In the context of this discussion, however, the question is whether the broader social consequences of the medical effects of the proposed therapy should be discussed with patients. One assumes that the direct effects of propranolol treatment on a patient's memories for a traumatic event would be discussed with the patient as this is the therapeutic objective. The remaining question is whether the indirect legal consequences of those direct therapeutic effects should also be discussed. There are reasons to think that such indirect consequences should be part of the risk disclosure process in the context of emerging treatments. For example, ethicists and lawyers have called for an obligation to disclose to patients the broader social, legal, and economic risks of learning genetic information about themselves in the context of genetic screening (Offitt and Thom 2007). Similar calls have been made to inform prospective research participants that one of the risks of participation is that "incidental findings" may be discovered in the process of genetic or imaging research and that this information may affect insurability or may disrupt family relationships (e.g., discovery of misattributed paternity) (Wolf et al. 2008; Smith Apold and Downie 2011). This obligation is arguably inherent in the major Canadian research ethics code, which requires researchers to have a plan approved by the ethics review board for the disclosure to participants of incidental findings (findings with "significant welfare implications. . .whether health-related, psychological or social") (TCPS 2 2010). Disclosure to prospective participants that incidental findings with significant welfare implications are anticipated ought to fit within the obligation to discuss the risks of participation. Some research ethics codes already address the issue of the disclosure to participants of the social, legal, and economic risks related to the genetic information that may be revealed during research (e.g., TCPS 2 2010; NHGRI 2012). While research is not the same as

therapeutic treatment, and so the scope of risk disclosure differs, perhaps novel treatments ought also to entail a broader scope of risk disclosure (i.e., that extends to social, economic, or legal consequences of the anticipated medical effects) than appears to be the case for well-established medical treatments.

The justification for expanded risk disclosure for emerging and experimental treatments is that these are the situations in which patients may be least capable of anticipating the indirect social, legal, or economic consequences of proposed treatments. Should the scope of risk disclosure be broadened to include such consequences where an emerging treatment may affect the fundamental building blocks of the self (i.e., cognitive functions and personality traits)? Schmitz-Luhn et al. (2012) raise the possibility that the legal requirements for risk disclosure and informed consent may be broader than normal in the context of deep brain stimulation because of the possibility of social consequences and personality change. They explore whether it is necessary to go beyond mentioning the possibility of these effects and to provide counseling to help the patient understand the potential psychosocial consequences in his or her particular case. In the case of memory dampening, should the risks of adverse legal consequences of treatment be included as part of the risk disclosure by physicians? It is true that physicians are not legally trained and may not be well placed to anticipate and advise on these matters. On the other hand, since many PTSD patients have suffered traumas that may foreseeably result in lawsuits or prosecutions, perhaps it is not unreasonable to expect physicians to be aware of and mention the issue, particularly since the timing of the propranolol treatment could be varied for someone who will likely serve as a witness.

Novel medical treatments often pose problems of this type, as the broader ramifications of a new treatment may be unclear to patients and physicians alike. As a novel treatment and its broader consequences become more familiar, it may be reasonable to expect patients to identify and weigh for themselves the significance of these broader consequences. One possible solution in the meantime is to make more use of practice guidelines for emerging treatments, some of which may direct physicians to raise broader social and legal ramifications with their patients. This is not unprecedented. For example, some clinical practice guidelines for assisted reproductive medicine include counseling about the psychosocial and legal aspects of using donor gametes (NHMRC 2007).

Who is Legally Responsible for Harmful Behavior that Flows from Brain Interventions such as Deep Brain Stimulation?

Brain interventions such as deep brain stimulation (DBS) occasionally produce dramatic unintended changes in mood, cognition, and behavior and may thus deeply influence a patient's personal identity. Reports from some DBS patients suggest that these changes can destabilize the subjective sense of self. Some patients are reported to have said "I don't feel like myself anymore," or "I feel like a robot" (Schüpbach et al. 2006). In a minority of patients, more significant psychiatric and behavioral problems may ensue, including severe depression,

hypersexuality, aggression, hypomania, and mania (Clausen 2010). In some cases, the person is so different that "out of character" criminality results. In one case, a hypomanic patient faced prosecution after he broke into a car in a crowded street (Mandat et al. 2006). Several interesting questions related to legal responsibility arise in this context. Are patients, and possibly their physicians, legally liable for harmful acts that a patient commits while under the influence of the stimulation?

A DBS patient who breaks the criminal law while under the influence of brain stimulation is likely to be held criminally responsible unless the impact of the stimulation is so severe that the patient meets the requirements for the defense of insanity (in Canada, "not criminally responsible by reason of mental disorder"). As for civil liability for actions while under the influence of DBS, legal systems vary in whether mental capacity is a requirement or not for liability in tort. In the United States, for example, people with mental illness or disability are usually responsible for both intentional torts and negligence (Dobbs 2000). In Canada, there is some uncertainty in the law, but some courts have excused mentally ill persons from liability for intentional torts and negligence where they are incapable of appreciating the nature and quality of their acts or of appreciating and discharging the duty of care they owed (Linden and Feldthusen 2006). However, in Canada, it is clear that a person who ought reasonably to foresee their own mental incapacity and who does nothing to avoid causing harm while in that incapable state will be held liable in negligence for harms caused while incapable. As a result, a DBS patient who is warned of the possibility of hypomania and fails to take steps to avoid causing harm when the stimulator is turned on may be held liable in negligence for damages caused (e.g., for dangerous driving).

As for the tort liability of physicians for harms caused by DBS patients as a result of the stimulation, it is useful to distinguish potential liability to the patient where the patient harms himself or herself and to third parties harmed by the patient. Starting with the patient who has harmed himself or herself, a physician could be liable to the DBS patient in two ways: First, the administration of DBS might fall below the requisite standard of care. This could occur, for example, if the particular patient was not suitable for DBS in the first place (e.g., the risks, including behavioral risks, outweighed the benefits for the patient), if the surgery was performed in a way that negligently enhanced the risk of harmful behavioral side effects, or if the follow-up monitoring and care were performed negligently in a way that failed to deal with harmful behavioral side effects. Second, a physician may be liable in negligence for failing to disclose material risks such as harmful behavioral consequences. Liability for inadequate risk disclosure would depend upon a showing that the lack of disclosure affected the decision. In Canada, this requires the patient to show that a reasonable person in the patient's position would not have gone ahead with the treatment if proper disclosure of the risks had been made (Picard and Robertson 2007).

The analysis is more challenging in the context of a physician's possible responsibilities to third parties. Where a defendant has some hand in "creating" a risky individual (e.g., by serving alcoholic drinks to the point of intoxication in

a bar, *Stewart v. Pettie* 1995; or by allowing a patient to drive home after an emotionally upsetting outpatient procedure, *MacPhail v. Desrosiers* 1998) or has a duty of supervision and control over a risky person (e.g., responsibility for an institutionalized patient with a mental illness, Picard and Robertson 2007), negligence law may impose liability on the defendant for harms caused by the risky individual to third parties. However, liability will follow only if the defendant fails to take reasonable steps to prevent the risky individual from causing harm.

In addition, physicians are sometimes held responsible if they fail to warn others (e.g., the police or third parties at risk) where a patient poses a reasonably foreseeable serious risk to third parties (e.g., *Tarasoff v. Regents of the University of California* 1976). The duty to warn collides with the duty of confidentiality to the patient, and so usually arises only where the danger is serious and imminent. Separate statutory notification requirements may also exist, as with the obligation in Ontario to notify the Ministry of Transportation of patients who are unfit to drive. The failure to comply with this statutory notification requirement may be used in a subsequent lawsuit against physicians by those injured by the patient (Picard and Robertson 2007).

As a result, it is conceivable that physicians may have some responsibility toward third parties to take reasonable steps to address serious behavioral side effects in their DBS patients. The outcome of such cases will depend very much on the specific facts of the case, including the seriousness of the behavioral effects in the particular patient, the foreseeability of harm caused by the patient, and the nature of the attempts to reduce the risk.

Conclusion

The law, neuroscience, and the concept of personal identity intersect in a multitude of interesting ways. This chapter has sought to organize this "area of intersection" using two well-established theoretical approaches to the concept of personal identity.

One of the traditional philosophical questions relating to personal identity is that of numerical personal identity, or the task of understanding what makes a person at one time the same person at another time and also what establishes the boundaries of one single person at one particular time. This latter concern, of synchronic numerical personal identity, is a central issue for the law in addressing dissociative identity disorder. In these cases, the law must decide what to do where an accused person claims that a "host" identity lacked knowledge or control over the actions of an "alter" identity. Neuroimaging research into dissociative identity disorder may one day supply additional diagnostic evidence and so may help to distinguish between genuine and feigned cases, but this alone will not resolve the difficult question of establishing legal responsibility in non-feigned cases of dissociative identity disorder. Another line of research into the overlap in mental functions of the various identities might have an effect on the law by undermining the idea that the identities are truly distinct and can be individually assessed for capacity and criminal

responsibility. This would tend to support a legal approach that looks at the accused person as having one disordered identity and that therefore applies the standard legal test for mental capacity to that single person, taking into consideration the extent and severity of the dissociative symptoms in assessing the accused's capacity at the time of the offence.

The chapter also adopts the broader vision of personal identity reflected in the neuroethics literature's concerns with the consequences for the "self" of various brain interventions. These concerns flow from a conceptualization of personal identity in the form of narrative identity or the self-conception that a person creates from the sum total of their experiences, values, and psychological attributes. A focus on changes in psychological attributes, including memories and personality traits, leads us to consider another set of legal issues posed by emerging neurological interventions. The chapter offers three questions of this type. First, we must consider the limits on the extent to which the law may coerce a person to accept "self"-changing rehabilitative brain interventions in the criminal context. This is a complex question that relies in part on understanding when and why changes to personal identity are beneficial or harmful. Second, should there be an expanded risk disclosure discussion during the informed consent process for medical treatment that may alter the "self" (e.g., self-constituting attributes such as memories)? It seems reasonable that as we embark on novel interventions of this type, an expanded discussion of the broader implications of those alterations is in order, and there are ways that this might be done without unfairly burdening physicians with unrealistic expectations that they anticipate the broad and sometimes subtle ramifications of such treatments. Third, brain interventions that cause changes in personality and behavior raise the challenging questions of responsibility where that behavior is potentially criminal.

History of Neuroscience and Neuroethics

History of Neuroscience and Neuroethics: Introduction

Abstract

The neurosciences have a long and fascinating history – one in which the bodily organ of the brain and its connection to theories about the soul and mind have triggered the interest of natural philosophers, physicians, researchers, as well as laypeople from ancient times to the modern period. As such, the history of the neurosciences – along with the recent history of neuroethics – incorporates wide perspectives from the history of philosophy and theology, the history of science and medicine, along with social, political, and cultural histories. This section will introduce the reader to several major topics in the complex history of ideas, theories, and neuroethical approaches to the structure and function of the brain and spinal cord. It first explores our modern knowledge about inflammatory and degenerative diseases of the brain, before eighteenth- to twentieth-century developments in basic neuroanatomy and neurophysiology are discussed. Mental health issues are also examined. There follows a description of the emergence of neurological surgery as a discipline towards the end of the nineteenth and beginning of the twentieth century, touching upon the particular new ethical

problems presented by operational manipulative and surgical approaches. The final two chapters explore the development of insulin and electroshock therapies, the history of new psycho- and neuropharmacological drugs since the 1950s, and the recent emergence of neuroimaging technologies – such as computer tomography (CT), functional magnetic resonance imaging (fMRI), and positron emission tomography (PET). Their impact on the modern basic and clinical neurosciences will be described as well.

Introduction

The following section on the “history of neuroscience” for the “Handbook of Neuroethics” explores the long development of research and medico-scientific investigations into the brain and spinal cord. Such a historiographical overview can hardly be all encompassing, given the vastness of the research and clinical field, but some central landmark developments and transformations regarding the pursuit of knowledge in neuroscience are covered and explored with respect to their influence on the emergence of modern problems in the field of neuroethics. While trying to give here a sketch of some important foundations of brain anatomy and physiology, the emergence of clinical and surgical neurological sciences, particularly since the Early Modern Period, along with the innovative scientific accomplishments and methodologies emerging with the nineteenth century (see Coleman and Holmes 1988), this chapter attempts to shed light on the historical conditions that gave rise to the development of the new research field of “neuroscience” – as it appeared during the second half of the twentieth century. The socioeconomic, technological, and military contexts in which this special part of the modern life sciences itself became a “big science” are also highlighted.

Individual cultural and social backgrounds of the Western research endeavor in neurology, psychiatry, and later the neurosciences shall be investigated, giving meaningful attention to the way in which philosophical concepts, held by the public and the neuroscientists themselves, and practical and technological approaches to the brain and spinal cord influenced them. In mapping out the diverging historical episodes and various people and places in the long history of the neurosciences, the many side- and subdevelopments that occurred and their alignment with other research fields cannot be sufficiently covered in the five chapters of this section. Interested readers, however, who would like to know more about the changing cultural contexts of neurological and neuroscientific investigations, should refer to the more exhaustive accounts in the historiographical research literature (such as Brazier 1988; Finger 2000; Hagner 2000).

Discussion of the Individual Section Chapters

The individual chapters of this section focus on particular developments in the history of modern neuroscience and the related problems to which these have given

rise in the emerging field of neuroethics. Paul Foley's (University of Sydney, Australia) introductory chapter (▶ Chap. 29, "Parkinson's Disease and Movement Disorders: Historical and Ethical Perspectives"; ▶ Chap. 35, "Deep Brain Stimulation for Parkinson's Disease: Historical and Neuroethical Aspects"), for example, focuses on the study and treatment of movement disorders since the Early Modern Period as well as historical and ethical perspectives on Parkinson's disease since the nineteenth century. Foley gives a detailed review of both the diagnostic approaches to clinical phenomena related to diseases of the basal ganglia as well as their historical pharmacological therapies from the eighteenth century until the near present. He further shows that Parkinsonism affected a significant minority of elderly patients during much of human history, long before it had its modern definition – namely, as a progressive neurodegenerative disorder of the basal ganglia system of the brain and characterized through reduced dopamine levels in the corpus striatum structure of the diencephalon. Foley then presents suggestive evidence from various sources to this effect in the older literature, in patient files and from doctors' letters to their colleagues and patients. In his discussion, he dwells on precursor therapies such as ergot derivatives used since the Early Modern Period, other alkaloid therapies employed in the nineteenth century – beginning with atropine, hyoscine, scopolamine, and later the introduction of L-dopa – as well as various therapeutic approaches used during distinct phases. He also refers to the drastic infectious epidemic of encephalitis lethargica during the 1910s and 1920s.

The next chapter by Jean-Gael Barbara (Université Pierre et Marie Curie de Paris, France) (▶ Chap. 30, "History of Psychopharmacology: From Functional Restitution to Functional Enhancement") offers a short history of the development of psychopharmacology and early attempts to draw clearer diagnostic and therapeutic distinctions between diverse practices like drug administration to subjects of mental health institutions. Observations of the relationship between obvious somatic diseases and mentally ill patients through the longer course of the history of medicine are also made. Barbara then analyzes the development of the concept of psychopharmacology, as it appeared at the end of the eighteenth and the beginning of the nineteenth century, with more systematic and experimental investigations furthering pharmacological knowledge and artificial drug synthesis leading to closer examinations of the nature of the chemical substances and their influence on the treatment of mental diseases. This period marked an increased rationalization of psychopharmacological treatment options and understanding of underlying causal and physiological processes. Ethical discourses during the nineteenth century centered particularly around the problem of therapeutic nihilism – i.e., the refusal by contemporary physicians and pharmacists to use drugs, potions, and mixtures deemed harmful or at least ineffective – while issues of euthanasia were also discussed regarding instances of intractable pain, chronic and fatal diseases, as well as brain cancer and disseminated tuberculosis. In the third part of this chapter, Barbara addresses the rise of psychopharmacology as a discipline, which in turn gave rise to the increasing use of psychoactive drugs since the 1950s, as exemplified in the introduction of chlorpromazine, haloperidol, or reserpine. In each historical period discussed, multiple ethical questions arose regarding, for example, the specific risks

of the administered drugs, questions of addiction, and other adverse effects. Towards the end of the nineteenth century, clinical observations about mental diseases were more and more studied on the basis of systematic animal experimentation in physiology. Based on the innovative epistemology of experimental psychopharmacological research, complex clinical trial protocols and research techniques were developed, showing that this field of inquiry experienced intense progress while conversely raising multiple ethical problems which clinical neuroscience and psychiatry have been trying to solve ever since.

The third chapter by Delia Gavrus (McGill University, Montreal, Canada) (▶ Chap. 31, "Informed Consent and the History of Modern Neurosurgery") looks at human subject research in the history of neurosurgery and explores the long journey towards informed consent. Her chapter begins with an overview of the history of experimental approaches with human subjects in clinical and academic research settings from the late nineteenth to the mid-twentieth century, drawing specifically on foregoing work and publications by the American historians of science and medicine, Susan Lederer (1995) and Susan Reverby (2000). Gavrus then provides an introductory overview of the development of modern brain and spinal cord surgery, mentioning in that context new somatic therapies for mentally ill patients which gradually became available at the turn of the century. She proceeds to draw upon her prior work on brain and skull surgeries for criminals in the first decades of the twentieth century (Gavrus 2011), as these also gave rise to distinct ethical problems of their own. This article then explores the development of psychosurgery in the twentieth century (e.g., lobotomies, callosotomies, and nucleotomies) and raises the ethical issues that have been pointed out in the relevant scholarly research literature (see the work of Valenstein 1986; Pressmann 1998), as well as the changing doctor-patient relationship. Those changes influenced the ways in which neurologists, psychiatrists, and neurosurgeons informed their patients and test persons about the prognosis of their disease, the reach and depth of the treatment options, the nature of their proposed experimental and clinical treatment approaches, etc. This chapter ends on a note about the new psychosurgeries – deep brain stimulation, nerve tractomies, and destructive electrofrequency therapies.

Frank W. Stahnisch's (University of Calgary, Alberta, Canada) chapter, entitled "Non Restraint – Shock Therapies – Brain Stimulation Approaches: Patient Autonomy and the Emergence of Modern Neuropsychiatry," (▶ Chap. 32, "Nonrestraint, Shock Therapies, and Brain Stimulation Approaches: Patient Autonomy and the Emergence of Modern Neuropsychiatry") discusses the early development of patient-centered treatments in nineteenth-century psychiatry and the backlash towards physician-oriented oppressive treatment and research styles in biological psychiatry at the beginning of the twentieth century. It is another aim of this chapter to trace some of the modern neuromanipulative approaches from deep brain stimulation back into their historical development and to compare them with more outmoded approaches regarding the electrophysiological alteration of the human cortex and deep brain structures. In the second part of this chapter, an overview on the development of modern deep brain stimulation methods and some of their major ethical problem fields is given. The neuroethical issue of external influences on human minds is

addressed from quite different interdisciplinary perspectives, such as from the basic scientific and clinical fields, from biomedical ethics, and from the philosophy of mind and brain science. This chapter adds another view to the discussion by putting forward a history of medicine and neuroscience perspective regarding the ethical problems involved, focusing on the issue of medical manipulation during the technological development of modern biological psychiatry. It is shown that, following the Second World War, electrophysiological stimulation approaches were developed, which began to crucially change the functional capacity of the human brain. By means of a comparative analysis, it is argued that many contemporary debates which question neuroethical applications (Glannon 2007) are problematic in significant respects. Of major concern, for instance, is the increasingly blurred conceptual boundary that is furnished by the complex relationships between clinical research, therapeutic intention, and physiological restitution.

In the final chapter, Fernando Vidal (Universitat Autònoma de Barcelona, Spain) (▶ Chap. 33, "Historical and Ethical Perspectives of Modern Neuroimaging") looks at a particular kind of innovative research technology – neuroimaging – which has become somewhat synonymous with the most cutting-edge research profiles and approaches of the modern clinical neurosciences. As Vidal intriguingly argues, neuroethics has been intimately connected with neuroimaging, both in its development and the definition of its tasks, and especially to the widespread application of functional brain imaging technologies such as PET and fMRI. Neuroimaging itself, in particular its uses, interpretation, communication, media presence, and public understanding, developed as one of neuroethics' primary subjects. Moreover, key neuroethical issues such as brain privacy or the conceptualization of blame, responsibility, and human personhood in general have largely gained from neuroimaging the form under which neuroethics deals with them. The employment of neuroimaging techniques to investigate phenomena usually associated with research in the humanities and human sciences brought those phenomena into the orbit of neurobiological explanation. Neuroethics emerged in the context of such technology-driven intellectual and professional developments. Thus, more than just being an important stimulus for the rise of neuroethics or a particular source of neuroethical challenges, the spread of functional neuroimaging can be considered a condition which reveals the sheer possibility of the field of neuroethics, as this chapter convincingly states. In return, neuroethics has come to support the claim that the neurosciences, particularly by way of functional neuroimaging, will revolutionize "traditional" ways of understanding the human condition. To the extent that such a claim is debatable, neuroethics might benefit these days from examining its special relationship to neuroimaging.

Conclusion

The individual chapters in this section collectively introduce major landmark developments in the long history of neuroscience that will be intriguing to anyone interested in modern issues of neuroethics. They provide historical and factual background information and insights into the social and cultural context in which

problematic new developments arose in modern basic and clinical neuroscience. Furthermore, major areas of antagonism between science and patient autonomy, physicians' freedom of decision, and external medical and pharmaceutical market forces, as well as underlying changes in the accompanying philosophies of the mind-brain relationship, are mapped and analyzed. From modern perspectives, these areas have generated particular ethical concern and ongoing discussions in the research field of neuroethics.

Parkinson's Disease and Movement Disorders: Historical and Ethical Perspectives

Abstract

Therapeutic interventions employed in the management of extrapyramidal movement disorders have the potential to modify behavior, mood, and personality by virtue of the fact that the basal ganglia and dopaminergic neural systems affected by these disorders are also intimately involved in cognitive, emotional, and behavioral processes. The ethical implications of this situation, however, have received widespread attention only in recent years. Despite the sometimes negative changes in behavior that may ensue, the indubitable liberating motor benefits of dopamine replacement therapy employed to treat Parkinson's disease and the associated increase in personal freedom for the patient justify its employment. Neurotransplantation may in the future prove to be a useful approach that avoids such problems, but the current absence of a safe procedure militates against its use.

Introduction

Voluntary motor activity in humans is controlled by two distinct neural systems: partially conscious control by the *pyramidal motor system* projecting from the motor cortex via the spinal cord to the muscles; and the unconscious maintenance of posture, as well as fine adjustment and coordination of motor activity, by the *extrapyramidal motor system*. In popular usage the term "movement disorders" elicits images of paralysis caused by disruption of the spinal innervation of muscles (pyramidal nerve cell disease). Neurologists, however, employ the term for conditions in which control of muscular tone or coordination is persistently impaired or abolished, despite the fact that the muscle involved and its direct innervation by the motor cortex are essentially healthy. These movement disorders result from dysfunction of the extrapyramidal motor system, the most commonly encountered extrapyramidal motor syndromes being Parkinson's disease (prevalence of 1 % in those over 60 years of age), essential tremor (5 % in those over 60 years of age), and tic disorders (up to 1 % of general population, more common in children and adolescents). Similar symptoms can also be unwanted consequences of prescribed medication, such as the tardive dyskinesias that develop in the course of antipsychotic therapy.

Hyperkinetic extrapyramidal motor symptoms range from small amplitude involuntary movements, such as tremor and myoclonus, to the extravagant motor excursions of athetosis, ballism, and chorea; it includes both rhythmic movements (tremor) as well as less ordered motions (chorea, tics), as well as complex actions that might appear voluntary were they not contextually so obviously inappropriate (the writhing, rolling movements of athetosis, the postural contortions of the dystonias). The persistent inability to remain still ("akathisia") is also a hyperkinetic extrapyramidal symptom, while *hypokinetic* extrapyramidal symptoms include the *slowing* (bradykinesia) or *absence* (akinesia, catatonia) of movement, as well as postural rigidity and instability.

The major nuclei of the extrapyramidal motor system are the *basal ganglia* – including the striatum (putamen and caudatus), pallidum, substantia nigra (SN), and subthalamic nucleus (STN) – connected in a series of complex circuits with each other and with other parts of the central nervous system, including the thalamus and cerebral cortex. These nuclei are, however, not solely concerned with movement, but are also involved in processes of psychological function (including motivation and reward), emotion, and automatic behaviors. The consequence is that an extrapyramidal disorder is typically anything but a purely motor disorder, and therapeutic interventions targeting motor symptoms may thus have unintended consequences in the mental and personality spheres.

The neurologist is bound by the same ethical considerations as other physicians: to reduce as far as possible the suffering of their patients, while minimizing any additional harm. The specifically neuroethical element enters these considerations when faculties particular to the CNS are involved, especially identity and personality. This chapter will therefore focus upon the impact of the best studied movement disorder, Parkinson's disease (PD), and its therapy upon these functions. PD was long regarded as an essentially motor disease but is now recognized to be the

"*quintessential neuropsychiatric disorder*", as it was described in a paper that documented the explosion of publications concerning cognitive, emotional, and sleep aspects of PD literature during the past two decades (Weintraub and Burn 2011). Neither PD nor its therapy can be discussed without considering the psychiatric consequences of each.

This overview will commence with a brief survey of how movement disorders were regarded in the nineteenth and early twentieth centuries, partly to provide background to later developments, but primarily to illustrate that the close linkage between disorders of mind and movement was recognized long before the neurologic basis for this nexus was clarified.

Extrapyramidal Motor Symptoms Prior to the 1920s

The extrapyramidal system was defined during the early 1920s, a successor to concepts of the "striatal" or "myostatic system" that had evolved between the late nineteenth and early twentieth centuries (overview: Lotmar 1926). Movement disorders had naturally occurred prior to the twentieth century, but were often interpreted as more mental than motor disturbances. More flamboyant forms, in particular, might lack obvious purpose, but these intricate motor excursions, often reminiscent of normal complex movements, nonetheless conveyed an impression of voluntary execution that suggested they might be the products of a *disordered* mind, but nonetheless of a *mind*. The frequency of movement disorders (tics, abnormal postures, bizarre motions) in mental patients was noted in an analysis of the latter nineteenth century English asylum casebooks, specifically in those inmates retrospectively classified as "schizophrenic" (Turner 1992). Phenomena that would today be regarded as "extrapyramidal" constituted an important part of the evolving definition of schizophrenia until the 1930s, and motor and autonomic symptoms now regarded as characteristic for extrapyramidal motor disease were seen as typical for mental disease (see Steck 1926, 1927). This was also evident in Kraepelin's procrustean accommodation of catatonia within his 1899 definition of dementia praecox, while Bleuler (1911) could recognize schizophrenia on the basis of gait alone. Even today the popular stereotype of the "madman" includes abnormal postures, gait, and speech among its most prominent features.

Movement disorders prompted the question of what else a person who had lost hegemony over their own body might be capable. This was especially true in the context of contemporary public and scientific fascination with somnambulism and hypnosis, and with emerging concepts of an unconscious aspect to the human mind. Those suffering movement disorders were thus not only objects of psychiatric scrutiny, but also forensic subjects, and their segregation was regarded as justified even where there was no evidence that an individual might pose an immediate threat to others.

It was, indeed, one of the most prominent investigators of clinical hypnosis who dominated the next phase in the interpretation of movement disorders. Jean-Martin Charcot was highly regarded for his contributions to delineating neurological

disorders (including "Parkinson's disease", a term he introduced), but is today perhaps more broadly remembered for his demonstrations of *la grande hystérie* at the Salpêtrière asylum in Paris. In the idealized form of this disorder, the patient presented a series of involuntary movements and changes in muscular tone that occurred spontaneously or in response to a specific stimulus, such as the touching of "sensitive spots" on their bodies. The dramatic writhing and arching of the woman's body, sometimes combined with attitudes of "ecstasy", constituted the very image of "madness", but the seeming ability of Charcot to initiate and terminate these states at will attracted both the interest of the general public and the criticism of colleagues who argued that Charcot had hypnotized his patients – if inadvertently, by force of his authority – and that the *grande hystérie* was a clichéd performance produced by impressionable patients to fulfil the expectations of their doctor (overviews in Trillat 1986; Goetz et al. 1995).

Important for the present discussion is that the Salpêtrière women did not exhibit a random assortment of bizarre motions, but rather a limited repertoire that included indubitably extrapyramidal symptoms. These "imitations" were sufficiently convincing that they could only be distinguished from the "genuine" neurologic symptoms by trained clinicians only on the basis of subtle differences and knowledge of the history of the patient. It is probable that, in some cases, they were not imitations, but expressions of organic basal ganglia disease, as in many respects they resembled the unusual motor symptoms of a neuropsychiatric disorder that emerged only a generation after Charcot's death: encephalitis lethargica. In this sense they were allied to the "neurosis" concept, applied to symptoms or disorders presumed to have an as yet undiscovered neurologic basis (such as PD). The allocation of a symptom to "hysteria" or "neurosis" was to a great extent dependent upon the context in which the symptom was presented.

Encephalitis Lethargica: The Omnibus Extrapyramidal Disorder

By the time of the First World War movement disorders could be regarded as neurologic or psychogenic, depending upon the clinician and the context in which the disorder was presented. There was also a growing interest at this time in the existence of neural pathways, distinct from the classical motor tracts, that were involved in maintenance of posture and the fine tuning of voluntary movement, spurred on in particular by Strümpell's concept of the "amyostatic symptom complex" (Strümpell 1915; see also Stertz 1921; Bostroem 1922) – essentially consonant with the more recent "extrapyramidal motor disorder" – and the landmark explorations of striatal neuroanatomy and neuropathology by the Vogts (1919) (overview: Lotmar 1926).

At precisely this moment, a new disorder challenged the separation of neurology and psychiatry and underscored the close relationships between the two halves of clinical neuroscience with respect to movement disorders. Two major forms of acute *encephalitis lethargica* (EL) were described during the peak of the 1918–1924 epidemic: a somnolent-ophthalmoplegic form dominated by symptoms

related to the impact of infection upon lower cranial nerves and brainstem sleep regulation centers, and a hyperkinetic form that additionally involved more anterior brainstem centers and, possibly, the striatum.

More pertinent to the present discussion were the *post-acute* symptoms of EL. Most of the 85 % who survived acute EL developed *post-encephalitic parkinsonism* (PEP), distinguished from PD primarily by the younger age of onset (15–35 years), and the severe accompanying autonomic symptoms (such as sialorrhea and seborrhea). The motor symptom palette of PEP was also broader than hitherto described for PD, including a variety of hyperkinesias, such as *primary restlessness* or *akathisia*, as well as a variety of *paroxysmal dyskinesias*, abrupt changes of muscular tone associated with clonic muscular contractions, the intensity of which generally abated during sleep, but which were exacerbated by emotional states or voluntary activity: *dysbasia lordotica* (thrusting forward of the pelvis); *torsion dystonias*; *oculogyric crises* (fixation of the eyes in an extreme upward or downward gaze); *cramps and tics*; and *respiratory abnormalities* (rapid, shallow breathing, barking, yawning). *Excitomotor syndromes*, involving more variable and extensive involuntary movements, and stereotypic behaviors, interpreted as reflecting the release of normally suppressed reflexes or motor patterns from higher control, were also typical for post-acute EL patients (see Zingerle 1936).

Every type of extrapyramidal symptom previously described in movement disorders, schizophrenia, and hysteria was thus also observed in EL (reviewed: Stern 1928; Guillain and Mollaret 1932). Such patients would previously have often been classified as psychiatric cases, but the epidemiology and neuropathology of EL undermined the view that such symptoms were psychogenic, even where their genesis and presentation were modified by emotional factors, and strongly suggested that even complicated, coordinated hyperkinesias, despite an apparently psychiatric or intentional nature, were indicative of extrapyramidal dysfunction (reviewed: Lotmar 1926; Stern 1928; Guillain and Mollaret 1932).

The symptomatology of post-acute EL also involved complex mental disturbances, most notably *akinesia* (lack of motor initiative) and *bradyphrenia* (slowed mental functioning). Careful interrogation of patients indicated that the general immobility of these patients was derived from disturbed interactions between the initiative and executive aspects of volition, a function hitherto regarded as primarily associated with the frontal lobe of the cerebral cortex (reviewed: Foley 2012). Some EL patients also presented symptoms normally encountered in schizophrenia, including catatonia and hallucinations, or classic hysteria, including the temporary amelioration of exacerbation of symptoms by suggestion, emotional factors, or pressure to certain parts of the body – not to mention the bodily contortions, arching of the back, and facial grimaces that characterized *la grande hystérie* (reviewed: Runge 1928; Steck 1931). These phenomena provoked debates about the roles of subcortical centers in "genuine" schizophrenia and hysteria, with the suspicion uttered by some that psychiatric disease was an expression of disordered subcortical function or of the loss of higher control of ontogenetically ancient subcortical behavioral responses (see, for instance, Schilder 1922; Reichardt 1928).

These suspicions were intensified by the behavioral syndromes exhibited by children and young adults who had suffered EL: prior to the development of motor symptoms, they presented a change in personality marked by impulsiveness, mischief, loss of social inhibitions, and attention deficits, combined with a sense of detachment from their own actions. That is, these children could steal, assault, lie, even murder and rape, despite an intact moral sense; after committing any of these actions, the child was passionately remorseful and convincingly insisted that they had been compelled to act as they did. This fissure between the conscious will and actual behavior could persist into adulthood, should the degree of motor incapacity allow its expression (reviewed: Thiele 1926; Fleck 1927b; see also Makowski 1983). Even many older PEP patients without major psychiatric problems retained an element of childishness or silliness, and were also markedly "clingy" and open to suggestion (see, for instance Fleck 1927a). It was frequently later noted that they long retained an exaggerated desire to please their doctors, and were often responsive to any new approach, regardless of how effective it proved to be in the longer term (Foley 2003).

The question naturally arose as to whether such persons were legally culpable for their actions, and European legislators generally concluded that they were not, although in England the application of such leniency needed to overcome an often unsympathetic judiciary on a case-by-case basis, not always with success. The nature of EL meant that those who developed asocial behavioral syndromes were not improved by punitive measures, as the "conscious self" was divorced from the undesirable activities of the individual. This ethical and legal conundrum was a source of ongoing discussion and consternation throughout the 1920s, and was ultimately resolved only by the unexplained disappearance of EL by the late 1930s (review of social aspects of EL: Neustadt 1932).

The phenomenology of EL demonstrated that emotivity, motivation, and motion are intricately interwoven in the subcortical brain, that topographic and functional lesions of the basal ganglia have consequences for the personality and its integration. This was of great practical concern during the 1920s: for instance, the largest EL outbreak, that of 1924 in the United Kingdom, aroused concerns that the generation following the one decimated by the Great War might itself fall prey to an infection that robbed young people of their mental autonomy.

EL was the epitome of extrapyramidal illness as a neuropsychiatric disorder, bundling as it did many of the problems encountered in less extravagant movement disorders. Many aspects of post-acute EL found their echo in phenomena that confronted clinicians decades later during the "modern era" of PD therapy.

Options in the Therapy of Parkinson's Disease

For many decades there were few options for the treatment of PD: belladonna alkaloid preparations (including atropine and scopolamine) were employed on the basis of their calmative and sedative properties as the mainstays of symptomatic management from the late nineteenth century until the early 1950s, when they were largely supplanted by synthetic anticholinergic and antihistaminergic preparations.

These agents provided only a modicum of relief by reducing resting tremor, and at the cost of dry mouth, loss of ocular accommodation, and gastrointestinal motility problems (see Foley 2003).

Dopamine Replacement Therapies

The 1960 discovery of the striatal dopamine deficit caused by SN degeneration, ultimately resulting in reduced thalamic activation of the cortex, remains the major watershed in the history of PD therapy. The importance of nigral degeneration in parkinsonism had been recognized by the 1930s, largely as a result of the neuropathological material provided by EL, but this initially had no impact upon models of PD. It was only in 1957 that Swedish pharmacologist Arvid Carlsson found that the listlessness induced by catecholamine depletion in rabbits could be reversed by restoration of CNS dopamine levels through administration of the catecholamine precursor L-DOPA; he concluded that a dopamine deficiency might also underlie parkinsonian akinesia, for which there was no treatment. In Vienna, pharmacologist Oleh Hornykiewicz discovered that dopamine levels were indeed markedly reduced in the basal ganglia of parkinsonian patients, leading to the initiation of a daring human experiment in 1961: neurologist Walter Birkmayer intravenously administered L-DOPA to a severely afflicted parkinsonian patient, with results that exceeded expectations, ultimately leading to the installation of L-DOPA as the "gold standard" medication for PD (reviewed: Foley 2003).

Although L-DOPA therapy was later hailed as the first "rational PD therapy", it should not be overlooked that these initial experiments provided part of the evidence that established its rationality, a bidirectional relationship between the principle and its proof that blurred the distinction between basic and therapeutic research.

The procedure involved is unlikely to be repeated today: a pharmacologist and neurologist, on the basis of laboratory findings partly raised by the pharmacologist, initiate an impromptu medical trial without consulting medical authorities, without a comprehensive research plan, and with a chemical supplied by its manufacturer for use in animals; there was no ethics committee from which to seek approval. The manufacturer was, indeed, suspicious that the dramatic effects achieved in this uncontrolled experiment had less to do with their powder than with the charisma of Birkmayer. As it transpired, this was not the case, but the international breakthrough for L-DOPA was not secured until neurologist George Cotzias achieved positive results with oral DOPA in the United States. His work was, ironically, based on a false hypothesis (he aimed to increase melanin levels) and undertaken with rather more recklessness: he increased the dose until the desired effect was achieved, but also a great deal of unpleasantness:

> Sure, the patients are suffering, but hell, what they're going through ain't nothing compared to what I went through when I was a sergeant in the Royal Greek Army. When the patients reach the degree of suffering that I experienced as a sergeant in the Greek Army, then we'll stop the study. But right now there's too much at stake (cited by Foley 2003, p. 490).

The single-minded personalities of Birkmayer, who charmed his patients, and Cotzias, who dominated them, played decisive roles in establishing L-DOPA therapy. But both were representatives of the model of drug discovery and introduction that was already waning with the waxing dominance of pharmaceutical firms since 1945, but also with respect to the ethical framework for such research. The requirements for pharmaceutical trials in the United States stipulated by the Kefauver-Harris Amendment to the Food, Drug, and Cosmetic Act in 1962, for instance, included prior notification of the names of investigators and their qualifications, the structure and justification of the planned investigation, the obtaining of written informed consent from all patients and other subjects involved in trials. This prompted the New York neurologist Lewis Doshay, who had spearheaded the introduction of the synthetic anticholinergic agent Artane (benzhexol) into PD therapy in the early 1950s, to berate these changes as counterproductive and unnecessary:

> [in the 1950s] we had none of the current problems of obtaining written consent from the patients and their families, in order to test a new drug. Nor were we required to explain to them that it was a new and unknown drug containing many potentially dangerous side reactions. Our patients ... trusted us and were entirely confident that we would not give them anything to harm them. As a matter of fact, in the course of 30 years we had tested over 300 new drugs without a single instance of a serious toxic effect in thousands of patients (Doshay 1965).

In his opinion, a "*competent and careful investigator*" could achieve evaluations which were at least as informative as objective measuring devices by careful long-term, large-scale clinical investigations. Doshay was dismayed by the regulations which in his opinion had begun to hamper research, and felt that *"freedom of investigation no longer exists and the patients wait in vain for new and better remedies"* (Doshay 1965).

Whatever retrospective ethical doubts might be entertained, the unprecedented success of L-DOPA, improving not just the mobility of the sufferer but also allowing them a longer, more active life outside institutional care, subsequently led to the use of other agents that enhance CNS dopaminergic transmission (peripheral decarboxylase inhibitors, monoamine oxidase inhibitors (MAOI), dopamine receptor agonists), and *dopamine replacement therapy* (DRT) is today the dominant paradigm in the pharmacological therapy of PD (review of therapeutic options: Jankovic and Poewe 2012).

Nevertheless, L-DOPA does not cure PD – it neither arrests nor reverses the demise of the SN – and is itself associated with significant adverse events, the most significant being the development within a few years of abnormal involuntary movements (*tardive dyskinesias*), as well as of *on-off fluctuations* in the effectiveness of the agent. It was also suggested during the 1980s that L-DOPA itself might be cytotoxic (by increasing local oxidative stress), and thereby contribute to the progression of the disease, although this view is no longer so widely held. Given the undoubted benefits of L-DOPA therapy, and as the duration of PD prior to initiation of L-DOPA therapy is not associated with significant differences in response, it therefore seems advisable to postpone initiation of its use for as long as possible by employing alternative DRT measures, despite their being less effective and more expensive options, and not without their own problems.

In particular, dopamine receptor agonist medication (but not MAOI therapy alone) has been associated with *impulse control disorders* in 15–20 % of treated patients (Carter et al. 2011; also see reviews listed below). The most frequently reported forms include *increased sexual activity*, including proscribed practices, such as pedophilia; *problem gambling* or *shopping*; *compulsive eating*; and *excessive devotion to hobbies*. Increased tobacco, alcohol, and drug use, curiously, are rare. The most frequently encountered problem is pathologic gambling, the most popular gambling form being poker (slot) machines, although internet gambling is expected to assume a more prominent role in the future; younger patients and males are at particular risk (incidence as high as 9 %, compared with 0.5 % in the general population), consistent with a normally higher level of risk-taking and addictive behavior in these groups, and of especial significance when employing dopamine receptor agonists in early onset PD or restless legs syndrome. It is presumed that genetic, personality, and personal history factors (including a family history of addiction disorders) play at least a predisposing role, as do social factors, as indicated by the fact that gambling addiction is not as frequently a problem in societies where gambling is illegal (Appel-Cresswell and Stoessl 2011; Raja and Bentivoglio 2012).

As early as the late 1960s, it had been recognized that L-DOPA therapy was associated with increased libido in some patients (not always regarded as an adverse drug effect), but it is more commonly associated with *punding*, the persistent execution of particular stereotyped behaviors (such as cleaning, hoarding, grooming, or sorting), often related to previous work or hobbies; the term was coined by Swedish psychostimulant (amphetamine and cocaine) users to describe their own pointless perseverations. Punding is less disturbing for the patient than an impulse control disorder, as it does not involve invasive thoughts, but irritation may ensue should their stereotypic behavior be blocked or criticized. *Dopamine dysregulation syndrome* (DDS; also "hedonistic homeostatic dysregulation"), or excessive use of L-DOPA (c. 4 % of treated patients), resembles drug addiction in that patients persist with high dosing despite the resulting severe dyskinesias, and autonomic and mental withdrawal symptoms may accompany discontinuation or dose reduction.

DRT-treated PD patients may also present combinations of these behavioral abnormalities, and they are generally accompanied by more general psychiatric symptoms – particularly depression, anxiety, apathy, irritability, and executive impairment – symptoms that five in six non-demented Parkinson's disease patients, however, present within 7 years of diagnosis (review: Bonnet et al. 2012).

There is no doubt that these behaviors are triggered by DRT: the typical personality profile of PD patients is one of reserve, risk avoidance, and low addiction potential; further, the problem behavior typically normalizes following cessation of treatment. This does not mean that the patient is a priori not responsible for untoward behaviors; it might be argued, as did some authors in the case of EL behavioral syndromes, that the medication merely uncovered or released a pre-existing proclivity in the personality of the patient. For example, an English school headmaster was found to possess several thousand items of child pornography on his computer, only one of which had been downloaded prior to DRT: the question

arose as to whether this item was evidence of pedophilic tendencies prior to treatment (Carter et al. 2011). Another PD patient insisted that his fascination with anal intercourse during DRT was consistent with previously unexplored desires; after a change in medication, however, he not only lost his newfound interest, but was also ashamed that he had ever experienced such feelings (Carter et al. 2011).

DRT aims to simulate restoration of transmission in the nigrostriatal pathway, but can also be expected to have an impact upon a second major dopaminergic system, the *mesocortical-mesolimbic system*, excessive activity in which was implicated in the early 1960s in the etiology of psychosis, and which is now known to be involved in motivation, reward, and learning mechanisms. Although the concept of dopamine as a "reward" or "happiness chemical" is overly simplistic, this system is undoubtedly important for proper emotional performance as well as for goal-directed behavior, and genetic variations in dopamine-mediated transmission (release, reception, inactivation, re-uptake) are believed to be involved in predisposition to a variety of behavioral and emotional conditions, including impulsive-compulsive behaviors and depression. Further, dopaminergic neurons in the prefrontal cortex are involved via their regulation of information flow between CNS regions in memory and attention processes (Foley 2009). The ability to learn from positive outcomes is reported to be impaired in PD, contributing to their inertia, while DRT reduces the capacity for learning from negative experiences, so that correction of harmful behaviors and decision-making is impaired. Further, increased ventral striatal dopamine levels are associated with increased novelty- and reward -seeking (the left striatum is possibly more important in this respect, while the right is associated with harm minimization); as dopamine levels are not reduced in this region in PD, DRT may produce a relative "overdosage." Functional changes in the orbitofrontal cortex may be involved in the genesis of such behaviors. Nevertheless, it should be borne in mind that the neurobiology of impulse control disorders in general remains unsettled, so that the mechanisms underlying such behaviors in PD cannot be regarded as completely elucidated (Bodi et al. 2009; Cilia and van Eimeren 2011; Voon et al. 2011; Raja and Bentivoglio 2012).

Impulse control disorders and related conditions encountered during DRT can be catastrophic for the patient, with financial ruin, legal proceedings, and family breakdown not infrequent consequences of problem covert gambling or altered sexual behavior. They differ from the "bad behavior" of EL syndromes in that the PD patient generally identifies with their altered behavior during DRT, even should it be alien to their personality before and after therapy; that is, there is no perception that the behaviors are not "owned" by the patient. It is nonetheless difficult to clearly determine whether altered behaviors should be attributed to a change in personality, in volitional processes, or in the ability to suppress inappropriate impulses. In other words, the degree to which DRT medication occludes decision-making processes in general, thereby reducing the agency or autonomy of the patient, is unclear; that is, whether it not only increases the inclination to a particular behavior, but also reduces the ability to resist temptation. It is currently

thought that increased impulsiveness in DRT patients is combined with a lowered ability to censor their own behavior, so that recognition of reduced social and legal and competence is given. This might be compared with the impaired responsibility of a person induced by alcohol or other recreational drug that reduces the capacity for disciplined decision-making, except that the PD patient is taking prescribed medication for a serious medical condition, and does not enjoy the same degree of freedom to choose abstinence as a solution to their problem.

In practice this poses no major ethical problem, as these untoward effects can usually be resolved by switching the patient to another medication: further, the effectiveness of this approach confirms that the patient had not *chosen* to offend. Issues of "change of identity" have not been raised in connection with DRT (in contrast to DBS; see ▶ Chap. 35, "Deep Brain Stimulation for Parkinson's Disease: Historical and Neuroethical Aspects"), as it is clear that DRT only temporarily and reversibly alters aspects of personality in a manner comparable with other intoxicants, not the core personality of the patient.

As it is currently not possible to predict which patients will respond in this manner, it is imperative that DRT recipients' behavior be carefully monitored both by their family and their physicians, particularly as titration of dosage or switching to an alternative agonist alleviates the situation in most patients. As insight and decision-making are compromised, screening before and during medication is important. It may also be necessary to institute precautionary measures, such as transferring legal control of financial resources to guardians prior to initiation of therapy, particularly as patients with gambling problems are adept at concealing their often not inconsiderable losses. Whether medication control is required in DDS cases where excessive dosage does not result in problematic behaviors is questionable: if the patient accepts motor dyskinesias as the price of their abuse, restricting their freedom in order to preserve their capacity to make rational decisions is in itself problematic, particularly as "harm minimization" strategies, rather than abstinence, are currently popular with respect to illicit recreational drugs.

This issue of the responsibility of pharmaceutical manufacturers in this regard requires little philosophical analysis, as the manufacturer of *any* pharmaceutical agent is clearly obliged to disclose all *known* adverse effects of such agents prior to supply, and impulse control disorders certainly fall into this category. The role of dopaminergic systems in addiction and reward mechanisms were investigated as early as the 1970s, but it was not until the early 1990s that the major role of mesolimbic dopaminergic circuits in these areas was firmly established (review of current state of knowledge: Volkow et al. 2012). From this point it could be expected that any agent that modified dopaminergic tone might have an impact upon behavior. Courts have been petitioned by patient groups in several countries to decide whether manufacturers were aware of the behavioral risks associated with dopamine receptor agonists prior to their commercial release; this, however, is a forensic, not an ethical issue.

Neurotransplantation

Neurotransplantation (neural grafting) aims to replace nigrostriatal cells lost to degeneration, in the hope that appropriate connections with existing nerve cells ensue, re-establishing normal striatal function. Depending upon the degree to which the graft restored physiological dopamine release, it would allow reduction or even abolition of DRT, together with its negative correlates.

The idea was not entirely new when it was introduced in the late 1980s: a bovine striatum extract for the treatment of PD had been marketed in Germany in the late 1920s under the trade name "Striaphorin", taken as three tablets per day. Its chief proponent, Berlin neurologist Heinrich Rosin, reasoned that, if the material survived digestion, *"it is possible that degenerating centres in the central nervous system can still be rescued or that such centres that are liable to degeneration can be preserved by administration of healthy nervous substance with the same function"* (Rosin 1930). Despite some encouraging results, the expensive therapy was never adopted on a widespread basis, and any benefits can presumably be attributed more to the impressionability of PD patients than to its specific qualities. It may nevertheless be validly viewed as the conceptual precursor of more recent neurorestorative approaches.

The potential of neuronal grafts for alleviating the dopamine deficit had been explored during the 1970s in an animal model of parkinsonism, the 6-OHDA-lesioned rat, and the results were promising: the grafts survived and flourished, restoring normal striatal dopamine levels; normal electrophysiological firing patterns were established; and, most importantly, the motor deficits of the model were significantly ameliorated. The first clinical trials in PD patients followed in the early 1980s, employing cells from the patient's own catecholamine-synthesizing adrenal medulla tissue, but the results were unimpressive. This led to consideration of the use of human fetal nigral cells, not expectedly triggering an ethics debate. The Swedish Society of Medicine concluded that the strategy was conscionable if the decision to abort the fetus had been independent of the intended use of its cells, if the woman carrying the fetus provided consent, and if the entire procedure was conducted on a noncommercial basis. These guidelines later informed the first international guidelines for the ethical use of fetal tissue in transplantation (reviewed: Dunnett 2010).

Implantation of fetal ventral mesencephalic tissue (8–10 weeks postconception) into the putamen, the striatal component with the greatest dopamine loss in PD, proved to be quite successful: the grafts survived, striatal dopamine levels were increased, and there was a marked improvement in L-DOPA "on" time. These benefits were maintained for at least ten years after surgery. Further equally encouraging open-label studies followed, the findings of two double-blind, placebo-controlled studies instituted by the National Institutes of Health (USA), however, cast unexpectedly serious doubts on the future of neurotransplantation for PD: not only were the clinical benefits insignificant and graft survival poor, several patients developed severe "runaway graft-induced dyskinesias", initially ascribed to uncontrolled proliferation of the transplanted cells. Press reports garishly

declared that the therapy once hailed as a "miracle" had instead proved to be a nightmare. The relative success of deep brain stimulation at about the same time also undermined confidence in the risk-benefit balance of neurografting.

Transplantation trials have since been suspended until the problems brought to light by the NIH trials have been resolved. Research in this regard has included a shift in focus to deriving dopamine-producing cells from human embryonic stem cells (from embryos produced in the laboratory in the context of in vitro fertilization), thereby securing a better defined and more consistent cell source; the possibility of restoring stem cell-like properties to adult cells ("induced pluripotent stem cells") has also raised hopes that ethical reservations regarding material derived from human fetuses or embryos can be circumvented (Moreira and Palladino 2005; Brundin et al. 2010; Lindvall and Björklund 2011; Politis and Lindvall 2012).

Neurotransplantation can certainly not be equated with the psychosurgery of the 1950s, where large regions were denervated or removed without respect for the far-reaching consequences of such adventurism; modern neurografting is a cautious attempt to compensate pathological nerve loss in the brain (or spinal cord, where it does not incur the same rancor). Proponents indeed argue that local extracellular signalling directs differentiation and connection of the grafted cells, so that the process can be regarded as one of self-repair, whereby the applied allograft supplies only the raw materials.

If an effective, safe methodology can be developed, the next practical issue concerns the selection of patients for the new trials. Advanced disease patients experiencing unsatisfactory treatment response may seem the most appropriate candidates, as they are presumed to have less to lose than less afflicted patients. In the case of a therapy predicated upon self-restorative capacities, however, younger subjects would be preferable, especially as significant restoration may not be possible where the disorder is too far advanced.

The patient's attitude to risk would also be critical in assessing their suitability, given the potential for irreversible unforeseen complications of neural transplantation; full disclosure of the problems encountered in the NIH trials would be among the information supplied. Although general public uneasiness with respect to neurosurgery can be expected to dampen exaggerated enthusiasm for partaking in clinical trials of neurotransplantation, the patient may nonetheless be swayed by the neurologist's support or even enthusiasm for a new strategy, so that it is essential that explanation of the extent of the expected benefits and the irreversibility of the procedure, as well as the recording of consent, involve not just their neurologist but also other health specialists, dedicated counsellors, and the patient's family. This is particularly important as the motor benefit of neurotransplantation was not superior to standard L-DOPA therapy: *"Transplants improved objective signs of Parkinson's disease to the best effects of L-DOPA seen preoperatively. ... In subjects in whom transplants replaced the need for L-DOPA, the implants replicated the preoperative effects of L-DOPA, including dyskinesias in susceptible patients"* (Freed et al. 2011). That is, the major advantage lies in the convenience of reducing the need for exogenous L-DOPA, although total withdrawal was not possible in all cases.

Despite the conceptual support for the approach from animal studies and pre-2003 experience of mesencephalic grafting, the implantation of nerve cells into the human brain constitutes "human experimentation" to an even greater extent than deep brain stimulation therapy of PD, and this must also be explicitly explained to the patient and their family. Master et al. (2007) discussed the potential benefits to society of stem cell implants with regard to the gain in knowledge of the CNS, but the epistemic dividend of the technology should be handled cautiously; the medical benefit for the individual must remain paramount, particularly as the patient assumes the entire risk of the intervention (hemorrhage or infection during surgery; undesirable immunologic responses; inappropriate behavior of implanted cells, including tumor formation and cell migration), while their medical condition may not necessarily improve significantly even if surgery is successful.

Some authors have argued that neurotransplantation is little more than an attempted rehabilitation of the discredited practice of psychosurgery (see, for instance, Linke 1993; Moreira and Palladino 2005). Their stance is based upon their equation of the biological term "self" and the philosophical concept of "identity", arguing that the introduction of foreign tissue into the brain cannot be regarded as involving "self-repair", so that it necessarily alters the brain and consequently the identity associated with that brain (cf. detailed discussion of relevant issues by Frankfurt psychiatrist and philosopher Georg Northoff 1996, 2004). The current view of the dynamic relationship between CNS structure and function renders it unlikely that insertion of even a few thousand dopamine-releasing cells into the striatum would significantly affect a patient's sense of identity, as the cells are not additional to the normal complement, but essentially replace neurons lost at a site not associated with mental functions – which loss itself, incidentally, did not appear to directly impact upon the patient's sense of identity. Optimism is also encouraged by experience with striatal neurotransplantation to date, both by the absence of major psychiatric effects and by the observation that the positive and negative impacts of successful grafting are comparable in quality and quantity with those of normal L-DOPA therapy. This is not to deny that neurotransplantation in certain areas of the brain *could* modify personality or mental functioning, and thereby a patient's sense of identity. This, however, applies to any therapy, pharmacological, surgical, or psychological, that modulates dopaminergic transmission. Neurotransplantation might well be preferred to L-DOPA therapy precisely because it modifies dopaminergic parameters only at the site of insertion, and not in mesolimbic or cortical regions, as is the case for L-DOPA therapy.

A final ethical issue concerns the sham surgery involved in the "placebo-controlled trials" of transplantation (and also of newer strategies, such as gene implantation therapy). Sham surgery, including adjunct anesthetic, antibiotic, and immunosuppressive medication, clearly entails a greater risk to a patient than a placebo pill, and it has been argued that pre- and postsurgery comparisons of predefined parameters would be more appropriate. A particular problem associated with controlled surgical trials is that, despite the costs and inconvenience incurred, it must be possible for the subject to withdraw consent for

participation in the treatment or placebo arms of such a trial, even after surgery has commenced (brain surgery is normally conducted while the subject is conscious) (Rabins et al. 2009; further discussion: Dekkers and Boer 2001; Albin 2002; Frank et al. 2008; Brundin et al. 2010; Galpern et al. 2012; Swift and Huxtable 2013).

Deep Brain Stimulation

Considerable excitement has been generated in the past two decades by the management of parkinsonian symptoms by means of deep brain stimulation (DBS), usually directed at the subthalamic nucleus. This therapeutic approach employs electrical modification of basal ganglia circuit activity rather than direct modulation of dopaminergic transmission, although the latter is potentially involved in its mechanism of action. Concerns have been expressed that the alteration of mood often encountered as a by-product of this intervention may represent an inappropriate intrusion into or alteration of personality, and may also alter cognitive performance. The neuroethical issues associated with DBS therapy for PD will be discussed in detail in ► Chap. 35, "Deep Brain Stimulation for Parkinson's Disease: Historical and Neuroethical Aspects"; here it suffices to note that the psychiatric effects of DBS, in any case a last choice therapeutic strategy for PD, are generally not a cause of lasting concern for either the patients or their families, although adjustment to the improved mobility may be required of both parties. Ethical issues regarding the use of DBS to alter behavior or mood in non-neurological disease cannot be directly extrapolated to its specific application to the relief of movement disorders.

Overview of Neuroethics of Therapy for Parkinson's Disease

Four principles have established themselves in medical ethics as useful guides: patient autonomy, non-maleficence (do the patient no harm), beneficence, and justice or fairness (Beauchamp and Childress 1994).

Autonomy

Two major issues are included in this category, the first being that of the ability of the patient to provide *informed consent* for a medical procedure. PD patients have been reported since the 1920s to be more open to or even demanding for novel therapies, and to be more responsive to placebo treatments (including sham surgery), even on objective measures (such as neuroimaging), and this should be considered when discussing consent. Dementia is a feature of latter stage PD, but any therapy is typically initiated long before this point; it is, in any case, an exclusion criterion for the initiation of neurotransplantation and DBT therapies.

The PD patient can be expected to feel anxiety and perhaps desperation when initially diagnosed, and this anxiety will be revived and intensified with each perceived therapy failure. Further, their incomplete understanding of the nature of their disease impedes the ability of the patient to make a genuinely informed decision, but this applies to most interactions between layperson and physician.

Press reports of the "miracle" effects achieved by particular therapies complicate informed consent to an even greater extent, so that the possibility and nature of side effects must be carefully discussed, and the patient's immediate family involved in such discussions. The nature of the surgical techniques employed in PD also means that treatment will be provided by a limited number of centers, presumably including particularly confident advocates of these procedures. This contrasts with the situation for new medications; these can be trialled in a large number of patients in different settings, rapidly providing a considerable material concerning positive and adverse effects.

The second issue is whether *patient autonomy is compromised by therapy*. Patient autonomy is in general enhanced by therapy as a result of the improvement in motor freedom and enhanced mental initiative, but DRT therapies can elicit impulse control disorders in which the volitional freedom of the patient is challenged; this effect, which may reflect relief of disease-related behavioral inhibition, can be countermanded by modification of therapy.

Non-Maleficence

The *selection of therapy* must consider the nature of the therapy, the potential side-effects, and the current state of the patient. Surgical therapies are more invasive and, for the foreseeable future, more experimental than DRT therapies, so that caution must be exercised with respect to the physical, cognitive, and emotional status of the patient, including their attitudes to surgery and risk.

While PD is a grave disease, the risks associated with *not* implementing novel therapies are not so great that they justify unnecessarily risky alternatives (Kimmelman et al. 2009). As with other CNS-based disorders, the results of animal models can only be extrapolated to humans with reservations, so that these must be well-designed investigations capable of providing secure data, and their results interpreted conservatively. Human trials should be carefully designed to maximize both safety and their ability to yield reliable results that can guide further investigation, compensating the risks inherent in such trials. Finally, while such trials contribute to expanding knowledge of CNS function, such as the impact of certain interventions upon CNS dopaminergic parameters, clinical benefit for the patient remains the most important guiding principle when evaluating the risk-benefit relationship of an intervention.

Beneficence

This aspect is assured by implementing only those therapeutic strategies that both have a scientific basis – that is, there is a rational basis for the approach, in most cases derived from animal models of the disease in question – and controlled, double-blind trials have confirmed the clinical efficacy of the strategy (class I evidence).

The latter condition can naturally not be met by experimental treatment strategies, such as neurotransplantation, so that it is all the more important that clinical trials build upon a secure scientific basis, including extensive animal investigations. Clear consensus decision strategies with respect to treatment options have been established in both United States and Europe that also serve as guides elsewhere, and a conservative approach, commencing with the familiar L-DOPA and only proceeding to more invasive techniques only where absolutely necessary, minimizes the risk to patients (Fins 2009; Bell et al. 2011).

Justice

The major factor in this respect is the question of whether the benefit afforded by therapy justifies the costs involved. No physician or patient would contemplate a return to the pre-L-DOPA era, when PD often resulted in permanent physical incapacity and institutionalization. Conservative pharmacological therapy can thus be justified on this basis without further discussion, the only limitation being the financial capacity of the patient and their local health economy. Given their current developmental status, the question of whether the costs of surgical therapy justify their use in place of normal pharmacological therapy cannot yet be answered.

Ethical Challenges of the Early Identification of Parkinson's Disease Candidates

Genetic and brain imaging techniques provide researchers with the potential to discover nascent disease before clinical symptoms develop. Around 10 % of PD cases are genetically determined, and genetic counselling of family members is appropriate with regard to life and family planning, particularly as hetero-allelic inheritance may also be associated with dopaminergic dysfunction, while those with certain dominantly inherited mutations may remain healthy into old age. Nevertheless, the limited value of genetic testing in predicting outcome means that it is more important in research contexts than in the clinical setting (Appel-Cresswell and Stoessl 2011).

Brain imaging techniques can detect structural or functional abnormalities that may identify nascent disease in asymptomatic persons (family members of PD patients, or probands in a research setting). As with detection of relevant genetic mutations, the conundrum arises as to whether "healthy" persons should be informed about the detection of "abnormalities", even though it cannot be certain that the identified phenomena will lead to clinical disease, or may even prove, after further research, to be within the limits of normal physiological variation. As noted by Appel-Cresswell and Stoessl (2011), identifying a functional dopaminergic abnormality cannot be equated with discovering a tumor, as the significance of the former will be a matter of interpretation based on a complex of assumptions and technical features. This scenario must be thoroughly discussed before initiation of an investigation, and then discussed with those to be tested before seeking their consent for participation. The issue is particularly difficult because there are no

measures that could be recommended to the proband in response to such a result that would halt the course of any future disease (contrasting, for instance, with the discovery of a tumor or vascular issue for which medical treatment might be available), so that they pass from a situation of undisturbed ignorance to one of disconcerted ambiguity.

Unless the proband has indicated in advance that they would definitely wish to be advised of any abnormalities discovered – relatives of PD sufferers, or biomedical professionals, might participate in such studies, for example, specifically to ascertain their status – it is probably advisable to not disclose specific research findings. This approach, however, is still encumbered by the difficulty that many participants, knowing the purpose of the investigation in which they are participating, will presume that they will be told of *any* abnormalities, regardless of prior discussions.

Finally, the current state of knowledge militates against employing brain imaging techniques for the solution of legal questions regarding the etiology of parkinsonian conditions: the intentions of exploratory research remain separate from those of the application of its results until those findings have been substantiated.

Concluding Remarks

The yardstick of ethical behavior with respect to movement disorders, as for all medicine, is that the physician applies their available energy and resources to reducing the suffering of their patient, and to do so, as far as possible, without introducing new harm into their lives. Neuroethics can thereby be regarded as simply the application of general medical ethics to disorders and functions of the brain. The specifically neuroethical element of such discussions emerges where features and activities that are particular to the brain are involved: cognition, mood and emotion, and particularly identity and personality. Magic bullets, however, are rare in the clinical neurosciences, so that effective therapy is accompanied by "undesirable side-effects", and the question for both doctor and patient concerns the degree to which the latter is willing to accept these adverse consequences in order to alleviate existing discomfort. What appears to be a simple issue of the balance between positive and negative effects proves, in practice, to be somewhat more complicated, but many apparent ethical conundrums can be circumvented by retaining a pragmatic view of the patient as a real person with real medical problems that require solutions, and not to burden clinical decision-making with excessive application of metaphysical analysis of situations, when asking the patient how they felt would be more helpful.

Two principles can serve as rough guides: that therapy should be no more invasive than necessary and as reversible as possible; and that it should always be based upon the latest available understanding of both CNS function and the mechanisms of the strategy employed. No medical intervention is natural: strictly natural would be to allow PD patients to be reduced to immobile cripples, as was the

prospect for most prior to the advent of L-DOPA therapy. For the foreseeable future, there will be large gaps in our knowledge of the both PD and its neural substrate, as well as of the mode of action underlying the therapies applied. But neither these gaps nor the risk of side effects of any type justify outright prohibition of these interventions, as this would amount to therapeutic nihilism and deprive PD sufferers of any hope of relief: it is not to be expected that all the unknowns involved in PD and its treatment will be resolved in the foreseeable future. It would be as paternalistic to withhold promising advances in therapy because of residual uncertainty as it once was to run roughshod over individual patient concerns. One should also not underestimate the willingness of PD patients to participate in trials of new therapies, even in this air of uncertainty; the fact that they have PD means that they have already tolerated a great deal, and many are willing to take chances to advance both their own welfare and their quest for personal autonomy, as well as that of their fellow sufferers.

Abstract

This paper presents a very short history of psychopharmacology and attempts to make clear distinctions between (i) the practices of drug administration to insane subjects and the first observations of interactions between diseases and insanity during antiquity, (ii) the concept of psychopharmacology which appears at the end of the eighteenth century with the reform of ancient pharmacology focusing on general knowledge and the closer relations established between chemical substances and mental diseases within the first psychopharmacological rationalisms, and (iii) the rise of psychopharmacology as a discipline after the successes of a few advocates of pharmacological psychiatry in the early 1950s, with the successful uses of chlorpromazine, haloperidol, or reserpine. At each time period, ethical questions arose as to the dangers of these drugs, the addiction risks already being studied in the nineteenth century, the mental diseases which these drugs can induce being studied by means of animal experimentation, and the nonmedical uses of some drugs for enhancement behaviors and better life quality especially in children and students. The epistemology of psychopharmacology as a project arising in the early nineteenth century has developed continuously more complex methodologies for clinical trials. It is a field of intense progress and current inquiry which in return raises new ethical problems to be solved in future decades in order to guarantee progress in biological psychiatry to all social categories.

Introduction

The history of psychopharmacology is a complex historiographical inquiry, since the historical objects in question are often particularly ill-defined and ambiguous. This historical investigation concerns various time periods, from antiquity to the present time, and many scientific disciplines such as medicine, physiology, pharmacology, behavioral pharmacology, neurochemistry, and psychopharmacology. The particular histories published often make the error of comparing projects of distant time periods with disciplines developed later on.

A clear distinction should be made between the ancient pharmacologies of the mind from antiquity to the eighteenth century, the progress of pharmacological chemical synthesis, the evolution in therapeutic uses of drugs, and the various attempts of different periods in clinical trials on insane patients following methodologies progressively worked out with scientific criteria in the nineteenth century. Since each time period prepares the following, the rigorous historical investigation of psychopharmacology of the 1950s must avoid the opposite shortcoming of describing the sudden rise of a new science as being apparently in opposition to anterior knowledge.

Such a study is a sort of challenge as it requires to avoid these numerous pitfalls and forces the historian to define his objects better and distinguish the practices of psychopharmacology (the history of the uses of drugs, antiquity – eighteenth century), the concept of psychopharmacology (the behavioral and physiological study of ancient psychotropic drugs and newly synthesized ones in the nineteenth century), and the discipline of psychopharmacology (since the 1950s).

At first psychopharmacology appears to be characterized by an evident empiricism which raises many questions concerning the ethical issues of clinical trials and the shift from healing therapies to recent enhancement therapies (▶ Chap. 55, "Ethics in Psychiatry"; ▶ Chap. 73, "Research in Neuroenhancement"). However, the epistemological and ethical issues at stake at different time periods are very different, while many histories written by scientists or historians often have the drawback of connecting these issues with technical histories (uses and synthesis of drugs) and the history of ideas in a similar manner.

The modern historiographical approach to psychopharmacology should aim at working out these issues and better defining the limits of historical continuities and the real changes in each period, concerning not only science itself but especially epistemology and ethics. The present study only represents a short introduction to such a project hopefully to be expanded in the future.

From Antiquity to the Eighteenth Century

Scipion Pinel, the son of French nineteenth-century alienist Philippe Pinel, condemned the psychopharmacological practices of past centuries and their false empirical character which justified the use of drugs not by experience but by bringing into play outdated medical theories: " [. . .] One must regret the blind belief in disruptive medicines [based on past theories] [. . .] [These theories] are at times the coction of humours, the revulsion and repulsion of peccant matters in the brain, which these impatient doctors fight with powders, extracts, juleps, electuaries, potions, to defeat insanity; At other times, they prescribe bloodletting excessively, with no distinction of the causes and epoch of the disease, showing a medical doctrine full of prejudice, pedantry and ignorance, at various periods, often supported by the disastrous association of the name of a famous author." (Pinel 1837, p. 132; author's translation).

If therapeutic empiricism seems evident in the nineteenth and twentieth centuries, the psychopharmacological empiricism before the eighteenth century was mixed with the sophisticated doctrines of the giant medical systems.

Scientific psychopharmacological empiricism, such as the empiricism claimed by Claude Bernard, being used to combat these medical rationalisms and systems which evaded experience and experimentation, cannot easily be found in the periods previous to the nineteenth century, although local drug experimentation on the insane is not absent from antique and Arabic medicine.

What is often missing before the nineteenth century is the pharmacological empiricism based on novel psychopharmacological rationalisms which we define as the convergence between the development of new theoretical ideas on mental diseases, new rational explanations of the actions of drugs, and new practices of drug therapies. In the eighteenth century these convergences were often based on relations between outdated theories (theory of humors), past and new practices with weak evaluation of treatments, and poor attempts to consider new explanations of drug actions.

This is, in my opinion, the way one should consider psychopharmacology from antiquity to the eighteenth century, as it presents great geographical and chronological heterogeneity in this time period. Nevertheless, I will only consider here a few continuities in the psychopharmacological practices.

Greek medicine failed to build strong correspondences between a unified etiological conception of mental illness and a set of treatments tested with empirical therapeutic trials. However, the Hippocratic corpus described the organic etiology of some mental diseases, such as the "sacred disease" (epilepsy), and put forward the theory of humors to explain it, thus leading the way to possible drug treatments able to reduce the excess of phlegm in the brain as observed in the "epileptic goat."

In this area of medicine, Greek doctors gathered interesting clinical observations, noticed and studied further in the following centuries, in order to imagine new ways of treating mental diseases based on some interactions between insanity and pathologies such as fevers which sometimes improved mental health. These observations led to pharmacological treatments up to the twentieth century.

Therefore, if the concept of psychopharmacology was absent before the nineteenth century, a psychopharmacological thinking was on the way locally, in a nonsystematic but positive manner. This way of reasoning is relevant to our inquiry since it is in continuity with the treatment of the insane in the following centuries and because it remained heuristic until the rise of the concept of psychopharmacology in the nineteenth century.

The Concept of Psychopharmacology (Nineteenth Century)

The Rational Refusal of Drugs

At the end of the eighteenth century, Philippe Pinel (France), William Tuke (Great Britain), Vincenzo Chiarugi (Italy), and Benjamin Rush (United States) attempted to improve the conditions of confinement of the insane, leading the way to moral treatment. This turn came with a mainly moral conception of mental illness, although these doctors did not ignore, whenever possible, lesional causes and interactions with organic pathologies. Therefore, Pinel, for example, did not refrain from prescribing medications to improve the health of his patients. He himself used a short pharmacopoeia with favorite remedies such as wild blackberry and a mixture of camphor (Guislain 1826).

However, these different types of drugs of the early nineteenth century were rather inefficient, as was the massive use of herb tea in asylums until the first half of the twentieth century.

Scipion Pinel himself did not deny the value of medications, but the "monstrous polypharmacy" (his term) of the insane asylums was largely disastrous in his opinion, as was the immoderate use of bloodletting and the purgatives of ancient medicine.

Novel and Often Naive Rationalisms

Although insane asylums kept some specific traditions of old medications in very contrasted manners, with large differences of practices and opinions concerning the efficiency of drugs (Curchod 1845), a novel rationalism burst out to the scene at the turn of the nineteenth century, within a context where the conception of mental illness was divided into a moral etiology and an organic etiology.

In parallel to the rise of experimental psychology as a science as early as the 1820s (François Magendie, Pierre Flourens, or Luigi Rolando), some alienists with anatomopathological background, and those practicing autopsies, were convinced of the organic etiology of insanity, especially after Antoine Laurent Bayle (1799–1858) managed to demonstrate the organic and syphilitic origin of the general paralysis associated with insanity. These doctors adopted a complex epistemology of the anatomopathology of mental diseases, in line with Franz Joseph Gall, which demanded that primitive organic lesions should be searched for systematically in the autopsies of insane subjects (Barbara 2011a). They refused the concept of "pure functional lesion" which, however, surfaced at the end of the nineteenth century in Paris during the famous polemics on hysteria in the circles of Jean-Martin Charcot (Barbara 2011b).

Some of these alienists, such as Jacques-Joseph Moreau de Tours, developed interesting parallels between the organic action of chemical substances, such as cannabis, and insanity. When back from a journey in the East, Moreau de Tours made self-experimentation with cannabis and described the dreams associated with the drug which he equated with symptoms of insanity. Such a parallel was built over the central idea of the unicity of the etiology of nervous diseases and insanity, which Moreau de Tours suggested after his observations of the nervous and psychic effects of cannabis (Ledermann 1988). For Moreau, cannabis became a tool for experimental pathology, in the line of experimental physiology or, in Moreau's terms, of "mental pathogeny." Chemical substances became, as they were during or the psychopharmacological revolution of the 1950s, a means to build and discover new etiologies of mental illness. More specifically, for Moreau, the drug (cannabis) acted by way of a "substitutive action" on the cause of insanity (the "generator fact" of Moreau). The action of the drug restored the perturbation induced by the mental defect. Such a toxicological etiology of insanity can be seen as naive, but it represents a novel psychopharmacological way of thinking and a heuristic path to discovery opened by experimental physiology still widely used today. In the nineteenth century, a central theme of this strategy was the study of the mechanisms of poisons, such as the "nervous poison" curare (Barbara 2009).

New Drugs and New Clinical Trials

As early as the very beginning of the nineteenth century, new active plant alkaloids were chemically isolated and used in medicine: morphine, strychnine, caffeine, quinine, veratrine, atropine, or cocaine. Then the era of chemical

syntheses started with the famous leaderships of French, and then German chemists; the preparations of new bromides; and the chemical synthesis of chloral, chloroform, barbiturates, and paraldehyde. Novel animal experimentations tested the physiological actions of new and old drugs, such as Indian poisons used for hunting. In a second perspective, therapeutic trials were progressively widened to include insane subjects.

Pharmacology, experimental physiology, and novel toxicology were the scientific disciplines concerned. Before 1806, French physiologist, François Magendie, studied the physiological actions of upas and, some 10 years later, he experimented on its active principle, strychnine, just after its chemical isolation. As early as 1826, Pierre-Alexandre Charvet presented his dissertation entitled *Proposal on the mode of action of Opium in man and animals* at the French medical faculty. Deguise, Dupuy, and Leuret published their research on morphine in 1824 based on physiological and anatomopathological inquiry on animals (Chap. 134, "Animal Research and Ethics"). In the 1840s, Flourens also worked with a similar perspective on ether and chloroform. Experimental physiologists progressively defined these drugs as "nervous poisons," while they interpreted their actions with the scientific knowledge of nerve physiology (Barbara 2010).

All these studies did not proceed from a blind empiricism, although chance was a key factor in gathering Indian curares and upas. A profound knowledge of the power of these ancient poisons was scientifically used and tested experimentally and methodically. At the same time, rigorous clinical trials were developed from the end of the eighteenth century with old drugs, such as opium and morphine, and with a new concern in rationalizing pharmacy which tended to escape general knowledge and to develop regionally. Rational pharmacological trials can be found, however, earlier in the writings of some medieval and Arabic physicians. But the therapeutic indications of drugs varied greatly and agreements can hardly be found: before ether was used for anesthesia, it was used for gout, headache, or gastric spasms.

Therapeutic trials on the insane were made in some asylums, but few concerning drugs, and more generally involving moral treatments and physical therapies.

Some physicians experimented on the new sedative properties of the drugs studied by physiologists, directly on insane subjects, such as Thomas Smith Clouston (1887) who defined some basic scientific principles, some of them using statistics (Clouston 1863). Like Moreau de Tours, other physicians developed physiological and pharmacological ideas on insanity which justified their experimentations, such as the clinical trials of ether inhalation on epileptic patients in the 1840s.

The relations outlined by Greek doctors in antiquity between mental illness and diseases led to organicist conceptions of mental diseases favoring medications. German physician Wilhelm Griesinger widened the conception of a neuropathic origin of mental diseases which led to the idea that, if a central element of the nervous system is altered, medications can act on the nervous peripheral origins and fight the pathological processes invading the brain.

These approaches aiming at a more scientific rationalism compared to the previous decades, especially concerning the use of group subjects, control subjects, averages, and statistics, led to very little success, but to a better knowledge of sedation with available drugs until the 1940s.

However, during the 1860–1880s, physicians refined their practices of drug administration and developed different treatments for each nosographical category of mental diseases (Kraepelin 1899). Physicians generally followed the first recommendations on the cautious uses of drugs by François Magendie and viewed problems of toxicity and addiction more objectively (▶ Chap. 64, "What Is Addiction Neuroethics?"; ▶ Chap. 67, "Ethics Issues in the Treatment of Addiction").

Experiments and Newly Synthesized Drugs at the Turn of the Twentieth Century

The Introduction of Experimental Psychology in Psychiatry

At the turn of the twentieth century, a new scientific discipline, namely, experimental psychology, took over the objective inquiry of the effects of drugs on the mind by members of psychological faculties, in particular those interested in physiology and psychiatry, such as Kraepelin, Binet, and Féré.

In the 1880s, alienists, such as Clouston, claimed that medical psychology should help psychiatry in its new physiological perspective, thus evading the single previous philosophical framework that made psychology a branch of philosophy (Clouston 1887). This era marked by experimental physiology enabled experimental psychology and psychiatry to claim legitimacy for their medical investigations of the mind, evading the purely spiritualist perspective and taking the lessons of experimental psychologists such as Kraepelin, who trained with Wilhelm Wundt on the measure and interpretation of reaction times.

One of the new experimental approaches used Mosso's ergograph to study muscular fatigue and psychism, when a muscle is exhausted by intense work and nevertheless recruited again by a surge of lasting psychical force. This type of work was taken over by experimental psychologists and adopted in the study of the effects of drugs on psychism, in particular in learning and memory (Kraepelin, Benedict; see Lashley 1917). This was the way to the concept of behavioral pharmacology, a discipline adopting reflex tests, capacity tests of psychic faculties, control subjects, and simple statistical analyses.

The New Project of Psychobiology

Psychologists, alienists, and physiologists, individually or collectively and interdisciplinarily, not only claimed the experimental study of the mind, but they also advocated and tried novel forms of cooperation between disciplines in a new interdisciplinary perspective.

The term “psychobiology” never became the label of a clearly defined approach to psychology, but nevertheless, in the early twentieth century, it designated a diversity of opinions on what the relationship between experimental psychology and biology should be (Dunlap 1914).

According to Dewsbury, such opinions all shared a common point of view in their wish to bring psychology closer to biology in a holistic vision of the organism, in a manner analogous to the wish of biologists such as neurophysiologists Ralph Gerard (USA) or Alfred Fessard (France) to always keep in mind a “large picture” of the scientific problems, while biology turned to the systematic study of the elementary mechanisms of nervous phenomena (Edgar Adrian) and the minute molecular structures (Jean Nageotte, Francis O. Schmitt) (Dewsbury 1991).

Therefore, psychobiologists expressed the parallel wishes to preserve psychology from biological reductionism adopted uncritically, while taking advantage of the advances of biomedical disciplines. However, these psychobiological projects never became united, and were often aborted, such as the journal *Psychobiology* of K. Dunlap, with only two issues published in 1917 and 1920. Some of these projects, however, showed a great anticipation of the spirit of the neurosciences, as for example in France, where Henri Wallon created a *laboratoire de psychobiologie de l'enfant* (laboratory of child psychobiology) in a primary school in the Parisian suburbs in 1925 (Galifret 1979).

One can clearly see, in the perspective of Henri Wallon or that of K. Dunlap, the wish to take advantage of the advances in the study of the “histological details” in the field of psychology and in the desire to explicate their psychological and functional significance in the classical perspective of “physiological psychology.” In a broader perspective, those researchers claiming a psychobiological project did not put up any opposition between the study of forms and that of functions. These theoretical opinions favored studies on the effect of drugs on the psychic functions of normal subjects and diseased patients.

The new orientations of psychology in the 1920s and 1930s offered a new ground for interdisciplinary projects with biologists, physiologists, and physicians, some of them massively funded by the Rockefeller Foundation.

Psychopharmacology as a Project

In the 1920s, one can observe a burst of new studies on the effects of drugs on psychic faculties in animals and man. In this psychobiological context, David Israel Macht (1882–1961), pharmacologist of Russian origin at Johns Hopkins University, started experimental research on behavioral pharmacology on mice, developing a motor skill using a rope or circular mazes (Macht and Mora 1920). In one of his articles, he designated his emergent research program, in the line of the previous studies of experimental psychology of the 1890s, under the label “psychopharmacology,” although the term – or similar ones – had previously been used by others (Macht 1920). Macht defined his investigations very simply

as the study of the effects of drugs on psychological functions, with nothing really new from the previous psychopharmacological concept.

The interdisciplinary character of the study of Macht, and of others at the same time, clearly appeared since those projects involved not only physicians but also physiologists and pharmacologists. This is in striking opposition to the *Pharmakopsychologie* of Kraepelin which largely remained programmatic (Kraepelin 1892).

The Empiricism of Shock Therapies and Pharmacological Cures

In parallel to the development of a scientific project in psychiatry, a new path of therapeutic empiricism emerged at the turn of the twentieth century, aiming at understanding the effects of drugs on the mind.

Classical histories of biological psychiatry often focus on the first very successful psychiatric treatment: the malaria therapy of von Jauregg. However, the success of the treatment of neurosyphilis by inoculation of a malaria clone of low virulence in order to provoke fever represented the end product of a very long series of trials to induce a great variety of diseases, some of them dangerous, and to alleviate insanity.

One should reconsider those efficient clinical trials in the larger framework of the medical empiricism used in healing insanity, where physical and chemical treatments of all sorts were considered, such as the prolonged narcosis with bromide prescribed in order to reorganize functional nervous activities. This empiricism was characterized by the poor ethical concerns of trials and the lack of means to evaluate the benefit of treatments (▶ Chap. 58, “Relationship of Benefits to Risks in Psychiatric Research Interventions”). But scientific justifications are nevertheless elaborated with reference to a biomedical rationalism still based on nervous physiology and the emerging neuron doctrine.

Naive Rationalisms of Shock Therapies and Pharmacological Cures

The histories of shock therapies and prolonged pharmaceutical treatments used in psychiatry refer to other rationalisms responsible for the choice of inducing agents but also to the scientific explanation of their positive effects which justify their use – with little proof however.

The deep sleep therapy of Macleod and that of Epifanio using barbiturates and of Klaesi are all based on the belief that putting a stop to psychic activities in the nerve centers enables a better start upon wakening and the associated functional reorganization of neuronal connections, which explained the improvement of the observed psychic state of the patients, in a similar manner to the sleep theory proposed by Matthias Duval in the nineteenth century.

Hungarian anatomopathologist Meduna, trained in psychiatry, developed a psychobiological rationalism based on his histological investigations.

His observations of glial cells on epileptic and schizophrenic patients led him to think that if epilepsy induces a glial reaction, those cells tend to disappear in patients with schizophrenia. Meduna inferred that, in schizophrenic patients, glial cells could be reactivated with the artificial induction of epileptic convulsions. For this purpose, he used the intravenous administration of a convulsant, camphor, which led him to the rationalism of the Cardiazol treatment and convulsive therapy.

Sakel also used this rationalism at the turn of the twentieth century, along with the doctrine of Ramón y Cajal, in order to explain the benefit of the insulin treatment where the induction of a coma was believed to stop the degenerating processes accounting for altered cells and to enable the regeneration of their connections.

These types of reasoning were not much more elaborated than those of the malaria therapy, which leads epistemologists to infer that those researches were profoundly empirical. However, their empirical character rather results from ad hoc explanations, based on theoretical frameworks with mediate relations to the facts observed and which remain largely hypothetical.

The Beginning of Psychopharmacological Therapies

Limits of the Classical Pharmacology of the Mind

The pharmacology of mental diseases still remained very unsatisfactory until the 1950s. Some progress was made during the 1940s, but pharmacological innovation often continued to be homemade in small family industries, in spite of the development of large pharmaceutical groups at the international level.

The pharmacology of the mind was a poorly developed branch of psychiatry which nevertheless tried to make legitimate and somewhat efficient uses of narcosis, psychosurgery, and shock therapies on patients, with the aim of sedating them to secure psychotherapy and occupational therapy.

This failure to create new pharmacologically efficient treatments explains the impossibility of psychiatrists to find any consensus in the explanation of the effects of drugs and in psychogenic theories of mental diseases. This situation was more or less the one that prevailed over the previous centuries.

Locally, research groups managed to improve the efficiency or reduce the toxicity of some drugs, as was the case for specific classes of antiepileptic drugs, such as hydantoins. LSD or low doses of curare were tested on human subjects during the Second World War and on patients with mental diseases, while shock therapies still remained in wider use in asylums.

However, in the 1940s, some psychiatric departments embarked in therapeutic pharmacological empiricism (Jean Delay in France, Joel Elkes in Great Britain), after the rise of pharmaceutical industries opened an era of great enthusiasm in medicine, with dominant economical positions acquired during the Second World War, and following the discovery and massive use of new antibiotics, steroids, and antituberculosis drugs.

Therefore, the 1930s and 1940s should not be considered as a nonprofitable period for pharmacology and psychiatry, although the great success of neuroleptics in the 1950s overshadowed the new prescriptions of barbiturates, which replaced bromides, and the introduction of antiepileptics and anticonvulsants, such as phenytoin and trimethadione.

Psychiatry and Pharmaceutical Innovation

In the 1940s, a few neurologists and psychiatrists started experimentations on animals and new clinical trials on their patients, with little ethical commitments, trying new drugs and sometimes modifying the chemical structure of molecules themselves.

New effects of drugs unknown until then, but suggested by scarce and incomplete observation, were tested on specific categories of patients, as was the case for hydantoins, LSD, and disulfiram.

Past therapeutic empiricism met with a novel enthusiasm. Such empiricism had been forgotten when the therapeutic properties observed in the newly synthesized drugs were often different by far from those expected.

The path to discovery of the antihistaminic drugs included the phenothiazines previously recognized as insecticides, anthelminthic drugs, and then antimalaria drugs. The French military surgeon, Henri Laborit, experimented on the action of the antihistaminic properties of drugs in the potentiation of anesthesia to reduce anesthetic agent doses and prevent postsurgical shock and anesthetic shock.

Novel Psychopharmacological Rationalisms and the Neuroleptic Concept

New phenothiazines, the drugs which were to become later Antergan®, Neoantergan®, Phenergan®, and Multergan®, were synthesized in France in the 1940s and showed interesting antihistaminic properties. Phenergan® was tested at Sainte-Anne hospital in Paris by Dr. Paul Guiraud, as a sedative and hypnotic drug.

The fabric of the neuroleptic concept and the making of chlorpromazine as a drug against psychoses was a tortuous path pursued when Laborit, joined by French pharmacologist Pierre Huguenard, introduced a lytic cocktail with Phenergan®-Dipacol® which was shown to induce “artificial hibernation” and used to protect wounded soldiers from traumatic shock during the French Indochina War.

In these studies, Laborit tried a promethazine from the French pharmaceutical industry, Rhône-Poulenc, namely, chlorpromazine. Laborit rapidly noticed the antipsychotic action of the molecule which nevertheless remained unnoticed by psychiatrists from Val-de-Grâce military hospital where Laborit worked. Chance was partially involved in the discovery by Pierre Deniker and Jean Delay at Sainte-Anne hospital of the antipsychotic properties of chlorpromazine used alone,

at a time when drugs were generally used in combination or along with other physical treatments, such as sedation by lowering the body temperature with ice. The discovery occurred when the sedation with ice was abruptly interrupted, without notice to the doctors, because of an ice shortage in the hospital, but with no consequence on the benefit of the chlorpromazine treatment.

The Clinics of Chlorpromazine

The great, but slow, worldwide success of the discovery of the neuroleptic effect of chlorpromazine triggered enthusiasm among some pharmacologists and psychiatrists. The rationalism of antihistaminic drugs with expected antishock properties, given that they prevent anaphylactic shock, could lead other researchers to use a similar simple reasoning to find new psychiatric medications.

Delay visited laboratories abroad and was actively involved in the diffusion of his discovery of the effects of chlorpromazine. The molecule was progressively adopted in many countries and radically changed the life of psychiatric departments when the sedation of patients allowed social therapy.

Chlorpromazine slowly became a neuroleptic medication, but for numerous years after its discovery, it remained advertised, commercialized, and prescribed only as a sedative drug. The sedative chlorpromazine replaced hyoscine or amytal and led, however, to the withdrawal of polytherapies, since it was efficient when used alone. Chlorpromazine as a neuroleptic drug required many international meetings and international scientific prizes to advertise the new medication as such.

Therefore, one should always remember that a medication possesses an essence radically different from that of its constituting molecule. Chlorpromazine made possible the manufacture of Largactil® as a neuroleptic medication after 10 years of use worldwide.

Psychopharmacology as a scientific and medical discipline was born from this slow revolution, when a new drug was discovered to be efficient alone, and this ultimately paved the way to new explanations of psychosis. The revolution did not involve any radical change in pharmacological rationalism, but in the status of psychiatry in medicine and society with the new and markedly recognized efficacy of psychiatrists.

New Frameworks of Psychopharmacology and Theories

The discovery of haloperidol by Paul Janssen followed a rationalism different from that of chlorpromazine, but as simple and efficient, which was described by philosopher and historian Jean-Noël Missa after an interview with Janssen (Missa 2006). A friend of his, practicing high-level biking, informed him of the psychogenic effects of the amphetamines used for doping. Janssen felt he could discover anti-amphetamine drugs with possible antipsychotic effects, and this is how he managed to synthesize and test haloperidol. As for chlorpromazine, the new

molecule was first adopted as a sedative drug, and Janssen had to fight and convince psychiatrists to search specifically for the antipsychotic properties of the Largactil® commercialized form.

In this context, many psychiatrists tried their luck at testing old drugs or new molecules, such as reserpine, LSD, monoamine oxidase inhibitors, or benzodiazepines.

Psychiatrists, physiologists, and pharmacologists joined into common projects. In the USA, Seymour Kety became director of a new and important interdisciplinary psychiatric center at NIH. Those scientific interactions enabled common interpretations of the new efficient treatments and the rise of new biological theories of mental diseases based on the depletion of neurotransmitters (catecholaminergic theory of depression by Axelrod, serotoninergic theory of depression by George Ashcroft and Donald Eccleston) or the hypersensitivity to others (dopaminergic theory of psychosis by Carlson).

These new theories appeared a few years after the great controversy surrounding the chemical theory of neurotransmission and represented an extension of the latter in the medical field.

Psychopharmacology as a Scientific Discipline

Psychopharmacology as a discipline was born from a small group of psychiatrists, pharmacologists, neurochemists, one neurologist, and one surgeon who, in the 1940s, chose to follow the path of pharmacological empiricism to treat mental illness.

Only after the early successes of the 1940s, and mainly the 1950s, did this little community gather in international congresses and decided to found a new society, the *Collegium Internationale Psychopharmacologicum*.

From the very early 1950s onwards, they organized interdisciplinary meetings on psychiatric drugs and their mode of action (Jean Delay, 1950, Paris; US NAS, Seymour Kety, 1954; NIH, 1956, Ralph Gerard; Macy foundation, 1954–1959, Harold Abramson).

Following the introduction of radiolabelled neurotransmitters and the rise of neurochemistry, biological psychiatry, psychopharmacology, neurochemistry, and neuropharmacology became much more than individual disciplines. They became real scientific networks overlapping and paving the way to new forms of interdisciplinarity in the underground neuroscience project on its way in the late 1950s.

Ethics of Psychopharmacology

Ethics of Clinical Trials and Drug Evaluation

Chlorpromazine and haloperidol were tested on the patients of psychiatric departments with few ethical procedures, at a time when shock therapies were still in use, in spite of the Nuremberg code which was not strictly applied and in a scientific way not very far from standard physiological experimentation.

In September 1956, in Washington D.C., a meeting focused on psychopharmacology and the problems in evaluation, under the presidency of Ralph Gerard. The main issues concerned scientific and ethical questions dealing with patient categories, the evaluation of treatment benefit, adequate statistical analyses, conflicts of interest, the risk of side effects, problems of the autonomy of subjects, and the equity of access to treatment among patients.

While psychopharmacology was progressing, local ethical committees were constituted in institutions in order to guarantee an evaluation independent of the actions of pharmaceutical companies. Historians and sociologists of science have shown how mental diseases and their treatments could be seen as social constructs dependent on the economy, the social characteristics of nations, the interests of pharmaceutical industries, and the degree of the infiltration of psychiatry by psychoanalysis.

Questions on the autonomy, consent, and the selection of patients are still complex today in the fields of psychopharmacology (Informed Consent in the Mentally Ill). A controversy still occurring today concerns the use of electroconvulsive therapy. Although the techniques have been used for decades and advocated as a safe method particularly suited to treat psychotic depressions, some patients report traumatizing memory loss. For each therapy specific issues should guarantee an equitable negotiation of the consent form between patients and doctors.

In order to test the negative side effects of treatments and their unsuspected psychological consequences, some psychiatrists have practiced autoexperimentation with electroshock. Those experiments have shown to the medical community deleterious psychological consequences, more pronounced than those which could be evaluated by simply recording the improvement in the psychiatric state of the patients. These practices helped to justify the inclusion of healthy subjects in clinical trials, and since 1976 the American College of Neuropsychopharmacology enounced some restrictions on the conditions concerning the inclusion of such subjects.

Enhancement

In the previous years, sociologists and philosophers have studied the social consumption of psychiatric drugs for enhancement of cognitive capacities, in particular among children and teenagers during schooling (▶ Chap. 75, “Neuroenhancement”; ▶ Chap. 80, “Reflections on Neuroenhancement”; ▶ Chap. 73, “Research in Neuroenhancement”).

In a more general manner, nonmedical psychiatric drug consumption is an old theme of nineteenth-century medicine with the denunciation of addiction risks (▶ Chap. 64, “What Is Addiction Neuroethics?”).

People are deceived when some drugs are advertised, by pharmaceutical companies and society, as efficient treatments to a selective health problem. They consider science as a means to improve their quality of life but with no critical analysis, which should be adequately provided by professionals, physicians, drugstores, and drug makers.

France is the leader in antidepressant and anxiolytic drugs. Modafinil® is used in the US against narcolepsy and mild sleep disorders to enhance cognitive capacities.

The consumption of Ritaline® by children seems medically justified in only about 10 % of the subjects (▶ Chap. 106, "Neuroethical Issues in the Diagnosis and Treatment of Children with Mood and Behavioral Disturbances"; ▶ Chap. 73, "Research in Neuroenhancement").

Philosophers and ethicians tend to broaden the debate on these dangerous behaviors and present enhancement as a long-standing cultural reality. What really matters is the risk of selling drugs to consumers to combat, for example, memory loss, in the same manner as aspirin is provided against fever. The concepts of drug and enhancing agent are close and the boundary between the two is sometimes difficult to see for users who feel the right to correct minor impairments with pharmacological treatments without the help of responsible, not hypocritical, physicians.

Future Questions

The ethics of psychopharmacology remains a vast and often difficult domain of inquiry because of the dilemmas occurring on account of the application of antagonist principles of clinical trials which must simultaneously respect the autonomy of the subjects and guarantee a benefit, while giving access to new treatments to all social categories.

One of the major issues at stake deals with the trials of underrepresented social categories for which obtaining consent is complex, as for children (minors), teenagers (respect of their autonomy), pregnant women (risks for the baby), and minorities (possible lack of confidence and understanding). An ethical controversy concerns random trials with placebo controls using randomized withdrawals of patients. This is in opposition to the benefit principle, but it remains a key condition to evaluate this benefit.

For these reasons clinical trial methodologies become more and more complex and tend to be based on large international networks with rigorous follow-up meetings. These networks should remain independent, which is a difficulty given the necessary funding by industries and possible conflicts of interests.

The ethics of psychopharmacology is still an advanced domain of bioethics where much research and negotiation are still necessary. Historians of science are not excluded since a historical perspective can show very recent abuses and instrumentalizations of psychopharmacological knowledge by politicians, military institutions, and industries.

Informed Consent and the History of Modern Neurosurgery

Abstract

The concept of consent has a long history, being defined and understood in different ways over time. Specific historical events and debates, both internal and external to the medical profession, have shaped the manner in which experimentation on humans has been conducted and regulated. The adoption of laboratory approaches and an alliance with experimental science in the nineteenth century transformed the medical profession. Despite early attempts to articulate an ethics of experimentation, invasive and dangerous therapeutic procedures, including on the brain, were often tried on patients without their consent. The Nuremberg Code set important criteria, but egregious experimentation continued after the war. It was in the 1960s and 1970s, during the rights movement, and in the wake of public outrage over a number of revelations that a modern notion of informed consent began to take shape and that medical practices became subject to some external safeguards and regulations. The history of neurosurgery mirrors this more general story. After two decades of bold attempts to open the skull for a variety of afflictions, the development of neurosurgery as a medical specialty in the early twentieth century brought with it

an initial conservatism both in technique and in the range of conditions for which brain surgery was attempted. Starting in the 1930s, a radical interventionist ethos paved the way for the wide adoption of procedures such as lobotomy. A thorough scrutiny of these procedures came only in the 1970s, when review boards and other safeguards were put into place.

Introduction

As a practice, vocation, and profession, medicine has long been engaged in a spirited dialectic about ethics with society at large. The doctor-patient relationship pivots on an imbalance of power; issues of authority and trust shape the outcome of the therapeutic encounter, and over time doctors, patients, and regulators have responded in historically contingent ways to a complex set of challenges that pits investigation against care, healing against experiment. Focusing on the United States, in part because it was here that neurosurgery first developed as an organized medical specialty, this chapter will offer a brief review of the literature on the history of human experimentation, medical ethics, and informed consent in the nineteenth and twentieth centuries, and it will sketch the history of modern neurosurgery in relationship to these issues. Since neurosurgery involves the handling of the brain – the organ that in modernity is most closely associated with the self – this medical specialty has raised and will likely continue to raise deep questions about the ethics of treatment, especially in those cases in which cognitive and emotional impairment calls voluntary informed consent into question.

Human Experimentation and Informed Consent

Historians have argued that in the second half of the nineteenth century, the adoption of laboratory approaches and an alliance with experimental science transformed the medical profession, affecting not only the practice of medicine but also doctors' professional identity, their relationship with patients, and the public perception of medicine (Cunningham and Williams 1992; Schlich 2007; Shortt 1983; Warner 1986, 1991). Experiments had been conducted occasionally before this time (Trohler 2007), but doctors now started to view experimentation on patients and healthy individuals as highly desirable and necessary for medical progress, and an increasing number of medical journals and institutions began to cater to this enterprise. A concern with the ethics of experimentation was present at this time. The French physiologist Claude Bernard, who had published the influential book *An Introduction to the Study of Experimental Medicine* (1865), insisted that experiments that could harm a person should never be performed, while several decades later the celebrated physician William Osler emphasized not only safety, but also the consent of the patient (Rothman 1996).

However, despite these high-profile views, not only were invasive and dangerous therapeutic procedures tried on patients, but an enthusiasm for the new science

of bacteriology led some late nineteenth-century doctors to infect individuals (including themselves, orphan children, and those deemed to be "feebleminded") with syphilis, gonorrhea, smallpox, and other pathogens. Similar experiments were performed with thyroid extract, cancer grafts, and techniques such as lumbar puncture. The patients sometimes assented to the experiment; in many other cases they needed considerable persuasion, and in other cases they were deliberately led to believe that the procedure was part of the treatment. Physicians like Osler voiced disapproval when a few particularly egregious cases drew public attention, but for the most part, these kinds of studies continued to be performed and published in the medical literature. In the United States, reform-minded citizens raised concerns about such practices, and a lively antivivisectionist movement embraced what it considered to be the twin goals of animal and human protection from immoral experimenters. To the distress of the American Medical Association (AMA), which preferred to address the control of such practices internally, the antivivisectionists lobbied for federal legislation to regulate animal experimentation, an effort that led to Senate Committee hearings in 1900. The same year, a bill to regulate human experimentation was introduced but failed to become law. The medical profession strongly defended their research practices against the antivivisectionists, and, while rejecting external oversight, a few proposals for guidelines for clinical investigators and animal experimentation were put forward at the beginning of the twentieth century. The AMA code of ethics, however, was not revised to require voluntary consent until the 1940s (Lederer 1995). In other countries such guidelines were available earlier, although enforcement was a complicated issue. For instance in Germany, 1931 regulations that governed the introduction of new therapies emphasized informed consent, but such regulations did not affect the atrocious medical experimentation during the war.

In principle nineteenth- and early twentieth-century physicians subscribed to the idea that patients had to be informed before a dangerous procedure was undertaken. Nevertheless, this impulse to be truthful was balanced by a belief that it was a physician's duty not to divulge information that could unduly distress the patient and worsen his or her condition. Such benevolent deception had been enshrined since 1847 in the AMA code of ethics and had been heavily influenced by the work of the English physician Thomas Percival. At the beginning of the century, Percival had published a book that addressed medical conduct and ethics, emphasizing gentlemanly behavior towards patients and a balance between truthfulness and benevolent deception. Opinions about the necessity and the required depth of such deception varied, but most doctors sanctioned it, often with the complicity of patients and family members. It was only in the second half of the twentieth century that this became less acceptable to the profession and that patients began to take a more active role in inquiring about their treatment and prognosis (Lerner 2004; Rogers 2008; Sokol 2006).

Despite the fact that in the nineteenth and early twentieth centuries there were cases in which doctors were subjected to malpractice proceedings that hinged on some aspect of consent, and despite the fact that patients were informed to some extent about risks and did negotiate or decline their doctors' recommendation to undergo treatment, scholars have argued that patient autonomy and informed

consent are concepts that need to be historicized, since they acquired different meanings over time. For instance, when in 1822 the US army doctor William Beaumont retained the services of a man to study the process of digestion though an opening in his stomach that had been caused by an injury, the papers that were signed outlining the conditions under which the study was to proceed and the monetary compensation were more akin to an employment contract than to a document of informed consent (Lederer 2008; Pernick 1982; Powderly 2000).

At the turn of the twentieth century, Walter Reed's experiment in Cuba to understand the etiology of yellow fever has been seen by historians as one of the earliest precursors to our current understanding of informed consent. The researchers asked their subjects to read and sign a document outlining the potential risks, and they allowed the subjects to withdraw from the experiment at any time (Lederer 2008). In terms of legal precedent, basic informed consent in the United States has been traced to a handful of battery cases against doctors at the beginning of the twentieth century. These cases – the most cited of which is *Schloendorff v. Society of New York Hospitals* (1914) – anticipated later concepts of consent by addressing broader principles underlying the doctor-patient relationship such as the moral principle of respect for the patient's autonomy and self-determination. Nevertheless, scholars have noted that these early cases do not mean that a broad theory of consent became available immediately: legal theory develops incrementally, and in the common law system cases build upon each other further clarifying the law. It was only in 1957, a decade after the issuing of the Nuremberg Code, that the term "informed consent" was used in court in the case of *Salgo v. Leland Stanford Jr. University Board of Trustees* in which the judge ruled that doctors had a duty to disclose any facts that are necessary for the patient to give consent (Faden et al. 1986).

The Nuremberg Medical Trial, which concluded in the summer of 1947, was an unprecedented step in the effort to establish external guidelines addressing the ethical dimensions of clinical research. Although medical scientists, such as the American physiologists John West Thompson and Andrew Conway Ivy and the neurologist Leo Alexander, played a critical role in the investigation of war crimes and in the drafting of guidelines, the Nuremberg Code was external to the medical profession, being part of the verdict rendered by the tribunal in the trial of Nazi doctors who had engaged in biomedical experiments during WWII. A set of ten principles, the Code established the vital importance of voluntary consent and outlined sets of criteria for the conduct of medical experiments (Faden et al. 1986; Rothman 1996; Weindling 2001, 2004). Taking some inspiration from these principles, and after a long debate, the World Medical Association adopted in 1964 the Declaration of Helsinki as a set of safeguards for clinical research, although a glaring departure from the Nuremberg Code consisted in the fact that experimentation on those who could not give consent, such as children and prisoners, was actually sanctioned. Historians have suggested that this development reflected a strong American influence, which sought to protect the interests of pharmaceutical companies whose research on drugs and vaccines relied heavily on prison and reformatory populations (Lederer 2007).

In the immediate aftermath of the war, the AMA had also drafted Principles of Medical Ethics that required voluntary consent, prior testing on animals, and proper medical protection during the experiment. Nevertheless, despite the existence of these guidelines, many postwar researchers did not employ informed consent in their clinical studies and deliberately caused harm to their patients. The Tuskegee syphilis experiment (in which treatment for syphilis was withheld from poor African American patients in order to observe the course of the disease), the Guatemala prison experiment (in which inmates were deliberately infected with syphilis, gonorrhea, and chancroid), and the Willowbrook State School experiments (in which mentally disabled children were infected with strains of hepatitis) are among the most infamous examples of ethically egregious practices in the postwar era (Eckart 2006; Reverby 2009, 2011).

Scholars have argued that the critical period in which change occurred in the United States was between 1966 and 1976. The National Institutes of Health (NIH), which after the war had become the most important source of funding for biomedical research in the country, internally addressed potential ethical and legal concerns related to human experimentation, especially in light of the fact that experiments were increasingly using healthy subjects. The NIH adopted an internal practice of evaluating each research proposal with the help of a committee not involved in the project. Some historians have argued that this reliance on expert committees – which constituted in effect precursors to the Institutional Review Board (IRB) – reinforced professional and institutional autonomy (Stark 2012). In 1966, the NIH issued two cornerstone statements of policy that mandated signed informed consent and required proposed studies with human subjects to be reviewed by committee. At around the same time, following a doctor's whistle-blowing article about egregious practices in experimental research on human subjects and in a time period in which the rights movement was galvanizing American society, questions about human experimentation and medical decision-making were thrust into the public spotlight. In 1974 Congress passed the National Research Act, which created the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. The Commission studied wide-ranging issues such as the ethics of experimentation on prisoners, sterilization of the mentally disabled, and psychosurgery. The question of consent was explored, and the Commission concluded that informed consent had to be based on three principles: information, comprehension, and voluntariness. The role and functioning of IRBs were also investigated, and the Commission recommended guidelines that were enacted as federal regulations (Faden et al. 1986; Rothman 1991).

The Development of Neurological Surgery

The history of modern neurosurgery began to take shape in the latter part of the nineteenth century, and the ethical dimensions of this story closely parallel the developments outlined above. Trephining (i.e., drilling a hole in the skull) was a very old procedure and had been employed to different ends throughout history,

but modern surgeons tended to open the skull only in desperate cases of skull fracture caused by severe trauma, and usually an effort was made not to incise the membrane that covers the brain. A few developments in the nineteenth century made the procedure of opening the skull less dangerous. The discovery of anesthesia just before the middle of the century, followed shortly by antiseptic and eventually aseptic practices that reduced the risk of infection, gave surgeons greater latitude in the types of operations they could perform. During the same period, Paul Broca, Gustav Fritsch, Eduard Hitzig, John Hughlings Jackson, and others began to lay the experimental and theoretical foundations of localization, realizing that discrete functions (sensory, motor, language, etc.) were localized in discrete areas of the brain. In the context of these developments, a few European surgeons – William Macewen in Glasgow, Victor Horsley in London, and Ernst von Bergmann in Berlin – started to engage in a consistent attempt to open the skull of patients who suffered from neurological symptoms indicating the presence of tumors, abscesses, or blood clots (Dagi et al. 1997).

Ethical concerns about interference with the human brain were raised quite early on. One of the most criticized experiments of the last quarter of the nineteenth century, denounced by antivivisectionists and the medical profession alike, was Roberts Bartholow's investigation of the electrical excitability of the human brain at the Good Samaritan Hospital in Cincinnati, Ohio. In 1874, Bartholow admitted to his care a "feebleminded" young woman who suffered from a rodent ulcer that had left a gaping hole in her skull. The physician, who had been aware of the recent work of European experimenters on the localization of function, obtained the woman's assent to electrically stimulate her exposed brain by inserting electrodes at various points into the brain matter. He observed muscle contraction in different parts of her body at low intensities, but when he increased the intensity of the current, he caused the woman great distress, pain, and convulsions followed by coma. She died a few days later, and following Bartholow's published report of the case, a chorus of critics, including the American Medical Association, condemned not only the experiment but also, given the patient's mental abilities, Bartholow's claim that the patient had consented (Bartholow 1874; Lederer 1995; Morgan 1982).

Generally speaking, in the last decades of the nineteenth century, the surgical community embraced an interventionist ethos, and there were frequent denunciations – both from outside and inside the profession – of the wide prevalence of unnecessary procedures. Many surgeons had felt buoyed by the arrival of antiseptic and later aseptic measures, which could, at least in principle, dramatically decrease operative mortality rates. This interventionist ethos extended to procedures on the skull and brain (Scarff 1955). Not only were many surgeons eager to attempt the removal of a suspected tumor, but controversial new therapeutic procedures were also devised, as in the case of microcephaly – a diagnosis that was applied to babies and children who were thought to have small heads, who were considered to be "idiots" or "feebleminded," or who suffered from early ossification of the fontanels. The procedure, prevalent in Europe and North America, consisted of long incisions in or resections of these patients' skull on the theory that the brain

did not have room to grow or that pressure on the brain was responsible for some of the symptoms. In 1894 the New York doctor Abraham Jacobi, in an impassioned plea against overtreatment in medicine, recounted how over the past decade "the brains of operative surgeons were taken with the *furor operandi* on the brains of luckless children" (Jacobi 1894). He presented data that suggested the procedure's high mortality rate and denounced it on the principle that a doctor's first duty was to do no harm (Feinsod and Davis 2003).

A similar – and similarly controversial – procedure was tried on patients suffering from general paralysis of the insane. In order to relieve a supposed mechanical pressure compressing the brain, the surgeons permanently removed sections of the skull. In a debate in the *British Medical Journal*, critics seemed to balk at the severity of the operation and to doubt its utility, concluding that it was not justified (Berrios 1991, 1997; Shaw 1891; Tuke 1890). Questions of consent, or the patients' ability to give consent, were not raised, just as they had not been raised by Jacobi, suggesting that even for critics the most important issue at stake concerned medical judgment, rather than a patient's (or patient's relatives') ability to make an informed decision about such new and experimental procedures. The same was true of another late nineteenth-century operation devised by the Swiss psychiatrist Gottlieb Burckhardt, a doctor deeply committed to organicist explanations of mental illness who lesioned the cortex of patients exhibiting symptoms such as delusions, hallucinations, violence, and melancholia. One patient died, but Burckhardt claimed that three out of the remaining five subjects showed improvement. The medical community did not react positively to Burckhardt's procedure, and he stopped performing it (Berrios 1997; Whitaker et al. 1996).

In the United States surgeons tried brain and skull operations for a variety of conditions, including epilepsy, traumatic insanity, intractable headache, and even for criminality. Usually, some kind of consent was sought, and surgeons sometimes elaborated on the possible dangers involved in the procedure. For instance the St. Louis, Missouri, surgeon Emory Lanphear tried surgery in a case of "softening of the brain" and claimed that "I explained to [the patient] and to his doctors that no one besides myself had ever made the proposal to operate for cerebral softening, pure and simple, and that it was purely experimental, as well as not wholly without danger. The reply was that any danger would be encountered for a bare possibility of even incomplete relief from the fearful maddening sensations in his head" (Lanphear 1895). The patient, who had had a stroke several years previously, suffered from some paralysis, aphasia, headaches, and his intellect had been "somewhat affected." It is not clear, nor does Lanphear explain, to what extent the patient's consent could be taken at face value. Similarly unquestioned was the consent of criminals who were given the choice between a surgery to relieve "pressure on the brain" and a prison sentence (Gavrus 2011b, 2013).

As brain surgery became professionalized, a certain conservatism came to initially dominate the field. In the first two decades of the twentieth century, the influential American surgeon Harvey Cushing helped establish neurosurgery as a medical specialty by refining neurosurgical knowledge and technique while also founding a specialist society and creating an international school of neurosurgery by training

fellows from all over the world. Cushing favored a conservative approach that consisted in little damage to healthy brain tissue, minimal loss of blood, and intervention in only a limited number conditions, chiefly tumors, trauma, and trigeminal neuralgia (Bliss 2005; Gavrus 2011a; Greenblatt 2003; Greenblatt and Smith 1997).

Numerous letters sent by patients suggest that Cushing was generally revered and adored by those he treated (Bliss 2005). Doctors enjoyed a great deal of prestige and public trust in the first half of the twentieth century, a reality that began to decline in the 1960s and has continued to erode ever since (Burnham 1982; Imber 2008). The authority Cushing commanded as an elite surgeon likely gave his recommendation of treatment extraordinary weight. He did seek (unwritten) consent for the surgery, but it is difficult to assess the complexity of the conversation he might have had with the patients. More challenging for Cushing appeared to have been the process of obtaining the consent of the family for postmortem examinations. Such was the 1927 case of a young woman diagnosed with an occipital meningioma. After the surgery, once it became clear that her case was hopeless, one surgeon who worked with Cushing approached the patient's husband and asked for permission to perform an autopsy after her death. The surgeon noted in the patient's chart that "[the husband] is a very decent fellow but ruled by his feeling and my best efforts were wasted on him. His one definite grievance was that he had brought his wife to the hospital for observation with the distinct understanding that he was to talk to Dr. Cushing before any operation was performed and this was not accomplished. He said he would be glad to pay [the] additional bill that the hospital would send him but could under no circumstances consent to an autopsy and finally I was forced to let the matter drop" (Cohen-Gadol and Spencer 2007).

This difficulty in obtaining consent for autopsies was longstanding, and it appears that at least in the earlier period, Cushing may have sometimes resorted to unorthodox measures. In 1911, William Sharpe, who was at the time an assistant resident in surgery at Johns Hopkins, was sent by Cushing to perform an autopsy and remove a number of organs from a former acromegaly patient. Since the family had not given consent for the procedure, Cushing had bribed the priest instead, and Sharpe performed the autopsy stealthily, at the funeral parlor, the dead body already dressed for burial and laid in the coffin. Sharpe wrote that normally "[w]henever death occurred, every possible effort was made by Dr. Cushing to obtain the nearest relative's permission for a postmortem examination – not only to ascertain the cause of death but to confirm or disprove the preoperative diagnosis. Even without permission, it was still possible to "inspect" through the operative incision or, if need be, via the rectum." Sharpe felt that Cushing was often forced to spend too much time obtaining the relatives' consent after the patient died. A few years later, when Sharpe started his own practice in New York City, he instituted a system whereby the relative signed a consent form for the postmortem before the surgery was performed, in case the patient died under the knife. "In only three cases since that time has my request for this written permission been refused," Sharpe noted, "and in each of those three cases I therefore refused to operate" (Sharpe 1952).

Cushing's somewhat conservative attitude to brain surgery was supplanted by the much more aggressive and radical ethos of the second and third generations of

neurosurgeons. Sharpe himself operated on the brains of spastic paralysis patients. Starting in the 1930s, the younger neurosurgeons devised bolder, more experimental, and more extensive surgical procedures – such as the hemispherectomy (the removal of one cerebral hemisphere in some cases of epilepsy or tumor), the sectioning of the corpus callosum, and the bilateral removal of the medial temporal lobes (Scoville and Milner 1957). This last procedure was famously employed in the case of H.M., a patient who postsurgery developed profound anterograde amnesia and became a subject in memory research over the following decades. Neurosurgeons and neurologists also devised risky and painful experimental protocols for conditions such as epilepsy, and they treated institutionalized patients in a much more cavalier manner than they did extramural patients (Dwyer 2012). The surgeons enlarged their therapeutic repertoire considerably. They were now operating extensively in cases of epilepsy (the Montreal Neurological Institute, under Wilder Penfield, becoming the most famous center for such surgeries), hydrocephalus, hypertension, Parkinson's Disease, various pain disorders, Reynauld's Disease, and psychiatric conditions (Gavrus 2011b). The lobotomy would become the most contested of these new and aggressive procedures.

The Psychosurgery Challenge

In 1935, the Portuguese neurologist Egas Moniz, who was aware of experimental reports linking frontal lobe damage to a decrease in aggression and other emotional changes, devised a procedure he called prefrontal leukotomy. Through two holes drilled into the skull, an instrument was introduced into the brain and rotated so that it cut nerve fibers connecting the frontal lobe to other areas of the brain. Moniz tried the procedure on a number of psychiatric patients and claimed that many had been cured or were substantially improved. In the United States, many second- and third-generation neurosurgeons embraced the procedure, having been personally encouraged to do so by the Yale physiologist John Fulton. The neurologist Walter Freeman, in particular, working at first with the neurosurgeon James Watts, zealously promoted lobotomy especially in cases of severe affective disorders. Freeman later devised the transorbital lobotomy, a more easily performed procedure in which the frontal lobe was reached though the eye socket. Tens of thousands of Americans were subjected to lobotomy, most of them before the mid 1950s, when alternatives such as the antipsychotic chlorpromazine became available and when reports identifying serious side effects cooled lobotomy's appeal. Its initial popularity was partly the result of a lack of alternative therapies for psychiatric patients hospitalized in overcrowded institutions. Since lobotomy was initially presented as an embodiment of modern scientific medicine, psychiatrists in state institutions found it appealing, while patients and their families invested a lot of hope in its promise to cure mental illness. The Louisville neurosurgeon Glen Spurling, for example, wrote to Fulton in 1937 that he was "besieged by families of psychopathic patients to do this wonderful operation" (Spurling to Fulton, January 5, 1937, John Fulton Correspondence, Yale University

Archives). Even psychodynamically oriented psychiatrists accepted the procedure and incorporated it into their practice (Pressman 1998; Raz 2008; Valenstein 1986, 1997).

Although a few critics had expressed opposition since its inception, lobotomy became seriously contested only in the 1970s, after it had long been supplanted by procedures touted to be more firmly anchored in anatomical and physiological knowledge – smaller, more localized lesions to healthy brain tissue, such as the cingulotomy in which fibers passing though the anterior cingulated gyrus were destroyed in severe cases of obsessive-compulsive disorder. However, when suggestions were made about the utility of such brain lesions in curbing violent tendencies, they were met by a rising public concern about social control and lack of patient autonomy. In the wake of an unprecedented debate that involved the government, professional organizations, and the public, the practice of psychosurgery underwent great changes. In 1973, the state of Oregon enacted legislation requiring the operation to be first approved by a Psychosurgery Review Board whose members determined if the treatment had clinical merit and if the patient or guardian had given voluntary and informed consent. California enacted even stricter laws mandating that the patient had to have the capacity for informed consent herself; no guardian could make that decision for the patient. In this increasingly charged legal environment, in 1977 the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research commissioned studies to verify the utility of psychosurgery and issued a report (1977) that did not recommend the banning of psychosurgery as some critics had hoped, but advised strict safeguards and regulations for its practice. Among other issues, the 1970s debate on psychosurgery raised ethical concerns about the irreversibility of the procedure, informed consent (especially in the case of involuntarily confined individuals), the constitutionality of review boards, the protection of patients, and the problem of using prisoners in research (Valenstein 1980a, b).

Conclusions: Ethics and Contemporary Neurosurgery

Following the sweeping changes that were occurring in the 1960s and 1970s, the leading professional neurosurgical organization in North America, the American Association of Neurological Surgeons, convened a committee for the first time to study and issue a code of ethics. The Neurosurgical Code emphasized beneficence, the autonomy of the individual, and justice. The president of the association expressed his hope that "the Code [...] can help us unravel the moral dilemmas that we face in our practice today, and which I fear will become increasingly numerous and complex" (Patterson 1986). Indeed, new techniques and experimental procedures such as deep brain stimulation, which was approved by the FDA in the 1990s for a variety of neurological and psychiatric conditions, continued to bring with them challenges to the ethical underpinnings of neurosurgical practice (Skuban et al. 2011). Similarly, the rapid development of functional neurosurgery – the branch of neurosurgery that uses neuroimaging techniques to target areas for ablation, stimulation, or other interventions – has raised questions about the ethics of

interference and the fine line between treatment and experiment. Most recently, debates about the ethics of brain function enhancement and brain-machine interface are drawing attention (Lipsman and Bernstein 2011). Voluntary informed consent continues to be debated in the professional literature, not only by bioethicists, but by neurosurgeons as well. Efforts continue to be made to evaluate the process of informed consent and to devise better ways of engaging patients in the process of decision-making (Kondziolka et al. 2006).

As this brief history demonstrates, consent is a concept that needs to be historicized, since its meaning and application have changed over time. The development of our contemporary understanding of voluntary informed consent has been a slow process influenced by specific historical events and debates, both internal and external to the medical profession. Historians, bioethicists, legal scholars, and, of course, doctors continue to theorize the concept of consent and to scrutinize the new developments in medical research and treatment that ignite fresh debates about the ethics of interfering with the human brain.

Nonrestraint, Shock Therapies, and Brain Stimulation Approaches: Patient Autonomy and the Emergence of Modern Neuropsychiatry

Abstract

This chapter discusses some early developments in patient-centered treatments in nineteenth-century psychiatry as well as the backlash towards physician-oriented and frequently oppressive treatment and research styles in biological psychiatry at the beginning of the twentieth century. The chapter also aims at tracing some of the modern neuromanipulative approaches of deep brain stimulation back to their historical origins and comparing them with more outmoded approaches of the electrophysiological alteration of the human cortex and deep brain structures. In the second part of this chapter, an overview on the development of modern deep brain stimulation methods and related ethical problem fields is provided. This chapter adds another perspective to the neuroethical discussion by putting forward history of medicine and neuroscience case examples regarding the ethical problems involved, focusing on the issue of medical manipulation during the technological development of modern biological

psychiatry. It is shown that, following to the Second World War, electrophysiological stimulation and shock approaches were developed, which began to crucially change the treatment options for mentally ill patients. By means of a comparative analysis, it is argued that many contemporary debates which question neuroethical applications are problematic in significant respects. Of major concern, in this regard, is the often blurred conceptual boundary that is furnished by the complex relationships between clinical research, therapeutic intentions, and the perspective on patient autonomy.

Introduction

Until the time of the French physician Philippe Pinel (1745–1826), who was instrumental in the process of unchaining the insane at the Bicêtre mental institution in Paris at the end of the eighteenth century, diagnostic and therapeutic options for patients with mental illness had been very poor and limited to contingent forms of care by the family, the local community, and legal guardians acting from philanthropic and charity perspectives (Ackerknecht 1968). With the advent of larger-scale hospitals and mental asylums during the middle of the nineteenth century and more specialized research approaches towards the infirmities and demands of the mentally ill, the repertoire of diagnostic techniques and therapeutic options increased largely towards the *Fin de Siècle* (Reiser 1978). Certainly, the development of nonrestraint measures of custodianship and caring ("freeing the mentally ill from their chains"), the introduction of physical therapies (water cures and electro-puncture therapy), as well as "modern" shock therapies (malaria fever cures, insulin, and electroconvulsive shock therapies) at the beginning of the twentieth century not only brought with them rising social concerns about the innovative practices in psychiatry but also led increasingly to redefinitions of medical ethics and the context in which these new diagnostic and therapeutic technologies became applied (Leahey 2000) (► Chap. 70, "Human Brain Research and Ethics").

The blessings of modernized treatment approaches of the mentally and nervously ill became themselves a major subject of ethical debates in psychiatry and neuroethics. Early and notorious shock therapies of the twentieth century have morphed into a paradigmatic example of the limits of medicine, showing how the best intentions of doctors and researchers can go ever so wrong, turning often into a curse for those already suffering in mental institutions (Pressman 1998). Social concerns about ethical behaviors and the doctor-patient relationship in psychiatry and related fields were frequently born out of the introduction of new healing technologies and institutionalized hospital care. Most bioethical discourses in this field – whether related to physical and shock therapies, the early use of deep brain stimulation (► Chap. 35, "Deep Brain Stimulation for Parkinson's Disease: Historical and Neuroethical Aspects"; ► Chap. 39, "Ethical Objections to Deep Brain Stimulation for Neuropsychiatric Disorders and Enhancement: A Critical Review") in psychiatric contexts, or the later introduction of psychoactive drugs and pharmaceutical treatments

(Shorter 2009) – centered around pivotal issues regarding external influences on test persons in research settings or on patients' autonomy in clinical hospital contexts (Lederer 1995; Roelcke 2004), as shall be further examined in the following sections of this chapter.

Nonrestraint Therapies Since the End of the Eighteenth Century

The European Enlightenment of the eighteenth century gave rise to new conceptualizations of "human rationality," "personhood," and the "mind-brain relationship" that were not simply of philosophical interest but integrated with dramatically changing social attitudes towards the lower classes, women, and children, as well as the mentally ill (Rousseau 1990) (▶ Chap. 58, "Relationship of Benefits to Risks in Psychiatric Research Interventions"). Contemporary forms of treatment for the mentally ill began to center on "moral therapeutic" approaches, which understood the deranged human mind as an effect of the often oppressive and harmful social conditions (Ackerknecht 1986). During the postrevolutionary period in French medicine, treatment of the mentally ill transitioned from traditional remedies in Christian and aristocratic social settings – e.g., bloodletting, emetics, and purging – towards political and medical therapies which had been promoted by Pinel and other reformers as the new moral treatment in psychiatry. Hospitals became now the predominant place for attempting to treat psychiatric patients, rather than custodial institutions in which the patients had been traditionally housed for years and even decades (Lindemann 1999). At the same time, more specialized medical education programs for mental and nervous illness were integrated in the hospitals; the predominant teaching style in medicine and psychiatry became practical instruction at the bedside vis-à-vis the patient (Weisz 1994).

These developments had social implications for the physician-patient relationship, which was vivibly transformed in the "hospital medicine context" of the early nineteenth century. The diagnostic process now moved away from being a rather mutual venture between the doctor and the patient, as the introduction of new forms of technological instruments, such as the stethoscope, the thermometer, and later the reflex hammer, began to create a physical and mental distance between doctors and their patients (Porter 1995). Physicians – and not soon after, the members of the new profession of psychiatry – began to standardize moral treatments for all patients and thereby further reduce the role of individuality and personality (Stahnisch 2012). The communication between patient and physician became increasingly minimal, as the patients were rendered primarily into objects for study ("patient material" in the language of the time) rather than as equal partners of the physician.

Nineteenth-century advancements in experimental physiology and anatomical pathology translated relatively quickly into significant changes in the field of neurological diagnostics and therapy (Brazier 1988), even while the clinical treatment options in the field of psychiatry or asylum care remained very much the same (Porter 2001). Particularly academic professors of psychiatry – in France and Germany – criticized the dominant role that asylums had assumed in psychiatry, as

they regarded them to be unacceptably overcrowded with their medical staff clinging to inappropriate forms of mechanical restraint (Engstrom 2004). Psychiatric reformers saw the contemporary asylums as lacking adequate ways of patient observation at early stages of mental and nervous disorders, while clinical research needed to become more rigorous and systematic. If one takes a closer look at de- and regenerative research endeavors, for example, then it becomes evident that broader social concepts infiltrated both basic research and clinical practice at the turn of the century: One of the most influential directions of such a knowledge transfer was the psychiatric concept of "neuropathy," which the Berlin doyen of brain psychiatry Wilhelm Griesinger (1817–1868) had introduced as a reinterpretation of psychiatric brain diseases (Engstrom 2004).

Together with German internist Carl Reinhold August Wunderlich (1815–1877) and the surgeon Wilhelm Roser (1817–1888), Griesinger held many programmatic concepts of modern medical practice as being based on the natural sciences. In his medical practice at the mental asylum of Winnenthal, where he wrote his famous handbook on "*Pathology and Therapy of the Illness of the Mind* " (1845), he came to side with the earlier French "nonrestraint movement" (Griesinger 1845). As Griesinger later saw it, research in psychiatry had rather stagnated still during the 1860s and revolved around abstract theories. These limitations should drive young scientists – such as the famous Sigmund Freud (1856–1939) from Vienna – to study hypnosis as an innovative therapeutic option for neurology under Jean-Martin Charcot (1825–1893) in Paris. Renewed interest in clinical research also led to a reemphasis in the use of quantification approaches, hospital graphs and charts, and the innovative creation of instruments, such as the recent electro-puncture devices, which Griesinger integrated into psychiatry (Stahnisch 2007).

When the social reformer Griesinger accepted a position at the Charité in Berlin in 1865, his patients were housed either in the wards of the medical clinic or, together with the syphilitics and sick prisoners (Temkin 1955), in a closed asylum. However, the board of directors offered Griesinger a neurological ward with the outpatient department at his disposal, and he soon separated the psychiatric from the neurological patients. He actively promoted his new approaches to psychiatric care, such as implementing hospital care for acute patients in the middle of the capital city, while establishing an "agrarian colony" for chronic patients in the suburban outskirts as forms of community-oriented psychiatry care (Sammet 1997).

The doyen of twentieth-century psychiatry, Munich professor Emil Kraepelin (1856–1926), was markedly influenced by Griesinger, while also criticizing many of the methodological steps that Griesinger had taken with the program of "brain psychiatry." For Emil Kraepelin, as for later followers of Griesinger, the pathogenic element of "irritable weakness" was the basic constitutional concept for nervous diseases (Hagner 2000). Kraepelin alluded here to French-Swiss Bénédict Adolphe Morel's (1809–1873) concept of nervous "degeneration," which the latter had published in his "Treatise on Physical, Intellectual and Moral Degeneration of the Human Race" (1857–1858). Brain psychiatrists' perspectives on hereditary "neuropathic dispositions" also reflected recent developments in sociocultural contexts of urbanization, industrialization, and the medical implications of the labor question. These issues were

now discussed by prominent psychiatrists and neurologists, such as Kraepelin, Hugo Wilhelm von Ziemssen (1829–1902), or Carl Westphal (1833–1902), focusing on "nervous degeneration" as a rhetorical device (Schmiedebach 2001).

Kraepelin introduced the concept of surveillance wards in the late 1880s, which became a major foundation of Germany's scientific preeminence in psychiatry by the mid-1890s. Patient files and diagnostic cards were introduced as essential tools of Kraepelin's nosology and as a reflection of his emphasis on epidemiological longitudinal analyses. With the support of the US Rockefeller Foundation, the German Research Institute for Psychiatry emerged as the most eminent research institute in the 1920s and 1930s. It also created the support basis for multiple editions of Kraepelin's classic "Handbook of Psychiatry" (1915) that became the founding basis of the "Diagnostic and Statistical Manual of Mental Disorders" (DSM) in Psychiatry (Engstrom and Weber 2007). These developments were typical for the unique situation of the German-speaking medical community, where neurology and psychiatry stayed united much longer than in the Anglo-Saxon and French contexts (Karenberg 2007). Attention should be drawn also to the particularities of modern psychosomatics, as it developed as a response to the medical reductionisms in the late nineteenth and early twentieth century, often associated with Swiss-German physician Georg Groddeck (1866–1934) (Danzer 1992). He developed a holistic approach integrated with elements of deep psychology, neurology, narrative literature, and physical therapy that avoided the limitations of nineteenth-century organ-centered medicine. Groddeck became very influential on later neurologists, such as Viktor von Weizsaecker (1886–1957), who is a particularly good example for his integration of philosophy, social psychiatry, and neuroscientific innovations into the "holistic neurology" of the Weimar Period (Harrington 1996). Just as the Weimar Republic generally aimed at a reunification and healing of its fragmented society, Viktor von Weizsaecker thought to transcend the individualized perspectives on the body and mind by applying social dimensions to medical therapeutics in his widely received work, "Social Disease and Social Healing," which emphasized medical reconstruction endeavors (new forms of rehabilitation, technological innovations in medical prosthetics, and long-term care options for the chronically ill veterans) (Weizsaecker 1930) (▶ Chap. 58, "Relationship of Benefits to Risks in Psychiatric Research Interventions").

The Development of Physical and Shock Therapies Since the End of the Nineteenth Century

The impact of the new physical and shock therapies since the end of the nineteenth century cannot be overstated from an ethics perspective. The important effects of international relationships in psychiatry and the clinical neurosciences along with the exodus of Jewish and oppositional neuroscientists from German-speaking countries in the 1930s also need to be emphasized. Many psychoanalysts, such as the Vienna-trained founder of modern psychosomatics Franz Gabriel Alexander (1891–1964), Frankfurt neurologist Leo Alexander (1905–1985), Sandor Radó (1890–1972) from Budapest, Helene Deutsch (1884–1982) from Vienna, or the German émigré

psychiatrist Charles Fischer (1902–1987), shaped North American psychiatry, mental health, and psychology in dramatic ways (Grob 1983). With regard to biological psychiatry, the "emigration" of insulin shock therapy, psychiatric genetics, and neurological synapse research and their relationship with basic neuroscience in North America cannot be underestimated. The double *volte-face* from the praise of psychoanalysis over brain psychiatry, its later antagonism with genetic and biological psychiatry, and finally repulsion towards it due to the advances in molecular medicine and neuroscience was another groundbreaking process in the history of American neuroscience (Magoun 2002).

According to Jack Pressman's "Last Resort: Psychosurgery and the Limits of Medicine" (1998), ongoing reevaluations of mental health practices towards the development of aggressive interventional psychiatric therapies were already underway during the first half of the 1930s (Pressman 1998). The new somatic forms of therapy were particularly associated with Egas Moniz' (1874–1955) psychosurgery in Lisbon and Ugo Cerletti (1877–1963) and Lucio Bini (1908–1964) at La Sapienza University in Italy in 1938, where electroshock convulsion therapy (ECT) developed (Pressman 1998). ECT quickly became more popular than insulin or Metrazol therapies because less hospital staff was needed and patients did not experience as many negative side effects when becoming unconscious almost immediately. Precautions were taken to ensure the right type of patients underwent ECT; those with a history of heart problems and arthritis were often excluded as candidates. When the shock was administered, patients experienced immediate convulsions and many stopped breathing momentarily. Up to half an hour following the treatment, patients were in a comatose state, in which they could become mentally confused and quite often physically agitated. Like other somatic treatments, there were respiratory and cardiac concerns, occurrence of fractures, and some symptoms of syndromes that appeared like the original mental disease being treated but were not (Bellak 1948). Similar to Metrazol shock therapy, ECT was found to be more effective in treating depressed patients versus the schizophrenics for which it was originally intended. By 1941, the primary course of treatment for a variety of mental illnesses was ECT or sometimes a combination of ECT and insulin coma therapy (Valenstein 1948).

When the Ukraine-born and Vienna-trained neurophysiologist Manfred Sakel (1900–1957) noticed the effect of hypoglycemic states in drug addicts, where insulin had positive effects on detoxification, he thought that he had discovered a new principle of psychiatric therapy by inducing artificial coma states in schizophrenia and severe depression. The success story of insulin therapy was largely the work of eminent Swiss psychiatrist Max Mueller (1894–1980), professor and chair of psychiatry at the University of Bern, who took over Sakel's procedure in his psychiatric asylum in Muensingen as form of "active therapy" vis-à-vis former noninvasive approaches, which subsequently became widely applied in major psychiatric centers in France, Spain, and Nazi Germany (Roelcke 2005). At the time a report of the Freiburg psychiatrist Egon Kueppers (1887–1935) to the Research Ministry of the *Reich* had been emphatically received, as it bolstered the Nazi medical philosophy which saw psychiatric patients merely as "useless eaters." The shock treatments thus offered an economical alternative to

hospital-based therapy, supplementing public health measures as applied to the "organism of the people" (Borck 2005). Sakel became later himself forced into North American exile after Austria was annexed to Nazi Germany in 1938. Once he reached the USA, he started to work as a staff-attending physician at the Harlem Valley State Hospital in New York, where his forced migration from Austria led to an unintended adaptation of shock therapies in American medical communities. The problem of large hospitalization numbers had also been recognized as a major strain on the American public health care system (Grob 1983). In this situation, the new shock therapies were perceived by psychiatrists in American and Canadian psychiatric clinics and asylums as a major technological form of relief (Pressman 1998). Where eugenics and psychiatric genetics had paved the conceptual and social way for a widespread application of the new shock therapies on the old continent, the belief in technological progress and social blessings there from provided an enabling ideology on the other side of the Atlantic, leading to a groundbreaking transformation in the development of modern neuroscience in North America (see specifically in Magoun 2002) (▶ Chap. 53, "Neural Transplantation and Medical Ethics: A Contemporary History of Moral Concerns Regarding Cerebral Stem Cell and Gene Therapy").

At this time, four somatic or physical treatments had been introduced to deal with what was seen as a rising problem of mental illness. Among these were malaria and insulin coma therapy, Metrazol shock therapy, and electroconvulsive shock therapy (Valenstein 1986). Despite the hope for these particular treatments, there were several downsides to the procedures, including extended comas, irregular cardiovascular and respiratory responses, and potential damage to the brain (Bellak 1948). Although some treatment protocols were deemed "successful" in a variety of cases, additional somatic treatments continued to be tested and adopted by the medical community in hopes of more effective solutions. Another treatment was Metrazol or Cardiazol shock therapy. This method was first tested in Budapest by László (Ladislaus von) Meduna (1896–1964) in 1934. Although the initial experiments used a variety of drugs, Meduna eventually found that the injection of Metrazol quickly induced convulsions and seemed to be effective in treating dementia praecox (schizophrenia) (see also Vidal and Ortega 2011). After injection, the convulsions only took 30 seconds to begin, but during that small period of time, patients experienced a very strong and antagonizing fear of death. As many as 30 treatments were recommended or until improvement was evident. Similar to insulin shock, cardiovascular problems often occurred. Another side effect was broken bones in the spine or other parts of the skeleton due to the severity of the muscular convulsions (Bellak 1948). Although this form of treatment was quickly adopted into regular treatment regimes, by 1938 the medical community found that Metrazol shock therapy was better suited for depressed rather than schizophrenic patients. Furthermore, with the advent of ECT, the use of Metrazol slowly declined, since ECT was perceived as a safer technique for patients (Valenstein 1986). The common link between the above three somatic treatments, and also the major ethical and social concern with them, was that they had limited effectiveness and schizophrenia was still not being treated as effectively as was desired by

patients, families, and physicians, while its treatments were perceived as very dangerous, with many side effects – despite the comforting rhetoric of contemporary psychiatrists and physicians (Valenstein 1948).

Another form of invasive and drastic treatment in clinical psychiatry and neurology that should also be mentioned here – as it had been developed in its precursor stages during the first decades of the twentieth century and gained later prominence in the 1940s and 1950s – is psychosurgery. Before psychosurgery took shape in its most well-known form today (as lobotomy operations), there were many surgeons and physicians who had begun to flirt with the idea that operational, neurosurgical means might be able to ameliorate mental disease. Most prominently mentioned in the literature is the Swiss psychiatrist and mental asylum director Gottlieb Burckhardt (1836–1907), who completed the first modern psychosurgical attempt in 1888. Inspired by the laboratory animal experiments on cortical function by the Berlin neurophysiologists Gustav Theodor Fritsch (1837–1927) and Eduard Hitzig (1839–1907) (Hagner 2000), Burckhardt's procedure attempted to remove portions of the cerebral cortex of half a dozen schizophrenic patients. However his procedure, in the following, proved to be fairly unpopular among medical practitioners because of the high bleeding and infection risks associated with it. The oppositional voices in the clinical community became increasingly louder, and Burckhardt was finally ordered by the respective district college of physicians to stop his clinical and research program (Stone 2001) (▶ Chap. 31, "Informed Consent and the History of Modern Neurosurgery").

Psychosurgery – as single surgical procedure or in combination with neurophysiological stimulation measures of the brain and spinal cord (Gavrus 2011) – is a form of neuropsychiatric treatment that was and still continues to be heavily criticized from both medical practitioners and patient advocates today. The term itself can be defined in a number of ways, but a dominant interpretation holds that all surgical procedures, which seek to manipulate the brain and spinal cord tissue in order to change higher (mostly cognitive) psychological functions aligned with specific psychiatric disorders, would be part of psychosurgery. Often these clinical phenomena present themselves without any prior morphological pathologies of the brain, while psychosurgery is seen as a restitution of functional circuits, maladaptations, or microscopical lesions (Feldman et al. 2001). The most commonly used procedures were cingulotomies in the 1920s, prefrontal lobotomies in the 1930s and 1940s, and thalamo- and nerve tractomies in the 1950s and 1960s (Alesch and Keith 2004). Today, the term describes operations such as cingulotomies used to treat severe obsessive compulsive disorders, while the discredited historical notion of "psychosurgery" has become almost obsolete (Glannon 2007) (▶ Chap. 59, "Ethics in Neurosurgery").

Twentieth-Century Brain Stimulation Contexts in Psychiatry and Nervous Diseases

Shortly before and after the Second World War, deep brain stimulation approaches were developed by neurologists and psychiatrists such as

Otfrid Foerster (1873–1941) at the University of Breslau in Germany, Wilder Penfield (1891–1976) at McGill University in Montreal, or Robert Galbraith Heath (1915–1999) at the Tulane School of Medicine in New Orleans, which eventually converged into various modern methods of deep brain stimulation as they are practiced today (Baumeister 2000) (▶ Chap. 35, "Deep Brain Stimulation for Parkinson's Disease: Historical and Neuroethical Aspects"; ▶ Chap. 39, "Ethical Objections to Deep Brain Stimulation for Neuropsychiatric Disorders and Enhancement: A Critical Review"). Many modern-day approaches (concepts, neurostimulatory procedures, but also ethical concerns) are based on the therapeutic and research foundations that were laid by such early neuroscientific teams. Modern neuroscientists often used very similar arguments to legitimize their research approaches to those of their predecessors, for example, in appealing to the "critical or incurable condition" of their patients or the alternative risks of other healing methods (Alesch and Keith 2004).

A more in-depth scrutiny of the early phase of brain stimulatory approaches from a historical perspective is certainly important since it demonstrates a rhetorical foundation which reaches back to the 1930s (Penfield 1978) and the early postwar period. These historical brain stimulatory developments – with their strong clinical research orientation – were finally able to lay the foundations for the current discussion of "a technological manipulation of the brain," which began raising important neuroethical questions many decades ago (Delgado 1969). The Canadian neurosurgeon Wilder Penfield learned his operative method and technique for neurostimulation principally during two extensive research periods with the neurological surgeon Otfrid Foerster at the Breslau clinical department for nervous diseases and psychiatry in 1928 and 1931 (Feindel 1998) – a fact which is little known. His German mentor had initially used the method of deep brain stimulation (stimulation of the septum of the diencephalon) for the treatment of schizophrenic patients and in individuals with posttraumatic epileptic disorders. Epileptic conditions following brain injuries were very common after the First World War, which had brought tens of thousands of patients with head wounds into neurological departments all over Europe and North America. Foerster's initial therapeutic approach would later be inversed in Penfield's program with its increasing emphasis on research into the localization of the human cerebral cortex. After returning from his tour of Europe, Penfield began successfully establishing a comparable and very modern clinical and research center at the Montreal Neurological Institute (Feindel 1992), where he closely monitored and recorded the movement effects, sensory perceptions, and psychological changes in his neurostimulated patients. During the neurosurgical operation these were kept fully conscious to avoid major damage of the brain under intraoperative stimulation, especially of the language, visual, and somatosensory centers. The electrophysiological studies on the brains of his patients in the operation theaters at the MNI built the foundation for Penfield's famous cortical cartographic map of the functional homunculus of motor and sensory cortical areas of the human brain (Finger 2000).

What is quite striking during this time, Penfield's patients (similar to those of Sakel, Cerletti, or Bini in their research on shock therapies) were not instructed

about the research intention of the general neuroscientific program, after they had agreed to receive surgical treatment to cure their conditions. This internalistic combination of neuroscientific investigations, epistemic conjectures, and (at the time paternalistic) ethical considerations did not really find its transparent introduction into the doctor-patient relationship before the 1960s. Instead ethical deliberations continued to be restricted to the individual consciousness and decision-making of the operating surgeon and some preliminary discussion with expert colleagues or hospital staff discussions which centered on the feasibility of the operations rather than on their immediate ethical concerns (Tone 2005). These paternalistic stances are omnipresent in Penfield's writings, although he barely touches on them in terms of a scholarly and critical reflection in his writings (Penfield 1977). Rather in the form of personal accounts and after discussions, such reflections can be found, as, for example, in the Proceedings of the Harvey Cushing Memorial Meetings of the Montreal Neurological Society of November 1939. Here, Penfield clearly embraced the teacher-pupil relation in clinical medicine and gives it visible priority vis-à-vis theoretical and philosophical reflections on the changes in the experimental nature of modern clinical neuroscience (Fins 2008).

In fact, not many sources can be identified that reveal Penfield's personal ethical views on medicine – and in this sense, he appears to be no exception to most of the neurosurgeons and research psychiatrists of the first half of the twentieth century. The paternalistic approach from a rather individualistic position in the ethical considerations of the Montreal neurosurgeon was quite typical for the immediate postwar period in medicine (see also Roelcke 2004). In general, Penfield was most interested in his ongoing research program and the investigation of the interrelation between the behavior-dependent and motor responses of his patients under intraoperative conditions (Penfield 1977). The primary concern of his approach, nevertheless, stayed with the surgical treatment of those areas of the brain which were seen as causally relevant in the etiology of epilepsies and tumors. It is quite remarkable, in retrospect, that although his program became so well known and Penfield's neurophysiological findings made a strong impression on the national and international scientific communities, there appears to be not much public discussion that accompanied these clinical research approaches during their advent (Fins 2008).

In contrast to Penfield's program, the public resonance which the neurostimulatory working group around Robert G. Heath at the biological psychiatry department of the Tulane School of Medicine in New Orleans garnered was enormous, developing into a central subject of media interest and provoking strong public controversy in the USA. At least in this instance, the disciplinary historiography has credited one of the co-workers of the Tulane group (Alesch and Mullet 2004), the neurosurgeon Donald E. Richardson (1919–1969), as one of the pioneers in the development of modern brain stimulation (Richardson 1980). The research in Louisiana, which commenced in the early 1950s, went undetected by the public only in its first few years. It was likewise scarcely heeded by the neuroscientific

community, probably because of the secluded nature of psychiatry and neurology communities at that time. For their ethical evaluation, it is not insignificant that nearly one hundred patients had been included in the clinical applications and the research program extended over the long time period of 30 years (Baumeister 2000). In 1996, Heath was even awarded the Gold Medal of the American Society of Biological Psychiatry, as he had "accomplished important work as a pioneer in the field of biological psychiatry" and "strongly enhanced our knowledge about the structural and functional relations of schizophrenic diseases to the brain." Over the three decades of this program, it is possible to find shifts in patient access, the doctor-patient relation, and to detect ethical reflections and rhetorical struggles within the contemporary scientific community, concerning the usefulness of Heath's procedure as being "a last desperate cure" (Fradelos 2008).

Heath – similar to Otfrid Foerster in Breslau – began his investigations within a psychiatric context: In a seventeen-year-old schizophrenic girl, Heath applied electrical currents, by means of deep brain electrodes, to the septum region of the diencephalon. Following the neurobiological understanding of the time, he wanted to "recalibrate" the functional inequality between the primitive brain regions of human development and complex cortical structures (Heath 1954). The patients were not specifically informed about the research character of these operations and most of them had psychiatric disease conditions, what for the Heath group seemed to legitimize such experiments, as the patients were unable to understand the complexity of the clinical trials and to give their autonomous consent to the physicians. The relatives and friends of these psychiatric patients became aware of the current research practices only after decades had passed, and the experiments began to attract greater media interest (Slattery 1990–1991). Not only did it seem that the patients were selected for their specific use in this research program of biological psychiatry – when explicit preference was given to severe cases in which no ethical consent could be obtained nor opposition expected – but also that the research results were being interpreted and presented in an overly positive light. It is interesting to note that in the research setting of the Tulane neurosurgeons, the electrodes for neurostimulation were not confined to the septum region. Instead, the Tulane researchers applied their electrodes to other brain regions "of interest," such as the thalamus or the nucleus caudatus, trying to find out what would happen in their patients. In so doing, these clinical researchers sought to derive further knowledge from the ad hoc intraoperative experiments, conceived when the skull of their patients lay open in front of them (Richerdson 1977).

It was mainly due to the new technological advances in medicine – more so than the sporadic forms of public media critique and patient activism – that major changes in clinical attitudes came about, a development which historical introductions in textbooks of deep brain stimulation often tend to neglect (Alesch and Mullett 2004). With the increasing use of psycho- and neuropharmacological substances, such as chlorpromazine in schizophrenia, valproate in epilepsy, and L-dopa in Parkinson's disease (▶ Chap. 30, "History of Psychopharmacology: From Functional Restitution to Functional Enhancement") brain stimulation methods lost their

appeal during the 1970s – in the United States and elsewhere (Pressman 1998). They became confined to narrow areas of functional restitution in therapy-resistant schizophrenias and intractable thalamic pain disorders.

Conclusion

The individual cases presented in this chapter expose some of the conceptual ambivalences in the complex relationship between therapeutic intentions – by biological psychiatrists and clinical neurologists – and the effects (social and personal) of medical research. Since the early days of hospitalizing the mentally ill and the shock therapies and electrostimulation programs from the 1900s to the 1930s, the gap between the physicians' healing intentions and the harm produced in patients and their relatives had been enormous (▶ Chap. 55, "Ethics in Psychiatry"). This general development was exacerbated largely through the research advances of the clinical neurosciences since the 1940s and 1950s, which have been examined in recent scholarly literature in the Science and Technology Studies (e.g., in Hayward 2001; Pickering 2004). The technological properties of the shock therapies and the neurostimulatory approaches make it clear that the invasive and manipulative operations on patients' central nervous system need to be regarded as two sides of the same biomedical coin: therapeutic technologies versus experimental instruments in tests with human subjects. It is precisely this amalgamation which adds further ethical questions to the problem of distinguishing between the epistemologies that clinical neuroscientists bring into their operation theaters, clinics, and test laboratories – for the better or worse (Roskies 2002).

By placing these developments in a comparative perspective, we see the often differing stances on patients' consent (Roelcke 2004), their relation to public perception (Reverby 2000), and the preparation of research funding requests to government agencies are all major factors in the development of new neuroethics concerns in the fields of psychiatry and clinical neuroscience (Dees 2004). In mapping out biomedical and technological advances, some significant connections, important co-developments, and continuing ethical problem areas become visible in this chapter. Furthermore, those ethical problems that relate to the changing historical relationship between the doctor and the patient raise central questions about the ethical status of informed consent in general. They point to the worrisome and often meandering course that reshaped the boundaries between neuroscientific research interests and clinical and therapeutic work (Farah and Wolpe 2004) (▶ Chap. 21, "What Is Normal? A Historical Survey and Neuroanthropological Perspective"). The individual historical examples from the rather recent and extended history of psychiatry and clinical neuroscience presented in this chapter make us aware of the continuingly problematic opposition between medical progress and patient ethics (Lederer 1995) as well as the intrinsically blurred conceptual boundary between clinical research, therapeutic intentions, and the autonomy of the individual patients within the framework of modern and ongoing biomedical progress (Heinrichs 2006) (▶ Chap. 25, "Impact of Brain Interventions on Personal Identity").

Historical and Ethical Perspectives of Modern Neuroimaging

Abstract

Both in its development and in the definition of its tasks, neuroethics has been intimately connected to neuroimaging, especially to the widespread application of functional brain imaging technologies such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). Neuroimaging itself, in particular its uses, interpretation, communication, media presence, and public understanding, has been one of neuroethics' primordial subjects. Moreover, key neuroethical issues, such as brain privacy or the conceptualization of blame, responsibility, and in general human personhood, have largely gained from neuroimaging the form under which neuroethics deals with them. The use of neuroimaging techniques to investigate phenomena usually associated with research in the humanities and human sciences brought those phenomena into the orbit of neurobiological explanation. Neuroethics emerged in the context of such technology-driven intellectual and professional developments. Thus, more

than an important stimulus for the development of neuroethics or a particular source of neuroethical challenges, the spread of functional neuroimaging can be considered as a condition of possibility of the field. In return, neuroethics supports the claim that the neurosciences, in particular by way of functional neuroimaging, will revolutionize "traditional" ways of understanding the human. To the extent that such a claim is debatable, neuroethics might benefit from examining its special relationship to neuroimaging.

Introduction

Unheard of in the 1990s, neuroethics required just a few years in the early 2000s to gain autonomy from bioethics, professionalize itself, and create networks, platforms, societies, journals, institutes, teaching, and research programs (Hoyer 2010; Conrad and De Vries 2012). Its main explicit goal is to examine and anticipate the ethical, social, and legal consequences of neuroscientific knowledge and its applications as well as to contribute to the ethics of neuroscience. In its development, history, and self-definition, neuroethics has been inherently connected to neuroimaging, especially to the increasingly widespread employment of functional brain imaging technologies such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI).

On the one hand, neuroimaging itself, as well as its interpretation, communication, media presence, and public understanding, has been one of neuroethics' primordial subjects. On the other hand, key neuroethical issues, such as "brain privacy," or the conceptualization of blame, responsibility, and in general human personhood, have gained from neuroimaging the form under which neuroethics deals with them. The use of neuroimaging techniques to investigate phenomena usually associated with research in the humanities and human sciences brought those phenomena into the orbit of neurobiological explanation. Neuroethics emerged in the context of such technology-driven intellectual developments. Thus, more than an important stimulus for the development of neuroethics or a particular source of conceptual and practical challenges, the spread of functional neuroimaging can be considered as a condition of possibility of the field.

Neuroimaging and Neuroethics: A Special Relationship

Coinciding with the "Decade of the Brain," the number of fMRI studies published in peer reviewed journals exploded from 1991 to 2001, and so did the number of journals publishing neuroimaging research. In parallel, from a small number of articles, mostly on sensory and motor tasks, the application of fMRI to human-science topics grew to 865 in 2001, with an average increase of 61 % per year during that period (Illes et al. 2003). By the end of 2004, 3,824 more articles had been published (Racine et al. 2005), and their coverage in the printed media

displayed the same trend (Illes et al. 2006) and has remained broadly optimistic (Racine et al. 2010b). By the middle of the decade, there was an avalanche of neuroimaging studies on topics with potential ethical, legal, social, and policy implications in four main areas: (1) altruism, empathy, decision-making, cooperation, and competition; (2) judging faces and races; (3) lying and deception; and (4) meditating and religious experience (Illes et al. 2006). Commercial products using neuroimaging results or devices appeared in the same period: major companies pay for neuromarketing services (Burkitt 2009); neurobics entrepreneurs offer resources for brain maintenance and enhancement purposes (Ortega 2011); private firms claim to have developed operative fMRI lie detectors (see Bizzi et al. 2009). Such scientific and extrascientific developments are a major motivation and source material for neuroethics (Racine et al. 2010a).

The expansion of neuroimaging and its connection to neuroethics can also be charted through the emergence of institutional and investigative programs whose names, from neuroaesthetics to neurotheology through neuroanthropology, neuroeconomics, neuroeducation, neurohistory, neurolaw, neuropsychoanalysis, and others, combine the prefix *neuro* with the name of a human or social science. Within these sciences, the "neuroscientific turn" (Feuerhahn and Mandressi 2011; Littlefield and Johnson 2012) occupies only a minority of professionals. Yet it contributes to motivate neuroethics. The new *neuro* disciplines, whose main tool is fMRI, aim to elucidate neurobiologically the phenomena they study. Moreover, they tend to assume that humans are essentially their brains, that ultimate explanations about human individual and collective behavior must be provided by brain research, and that such explanations challenge "traditional" beliefs about human nature and radically transform our views about it.

On the one hand, neuroethics is concerned with the results of those new research areas. On the other hand, as a field, it shares their assumptions, which it invoked in its successful effort to be considered a discipline separate from bioethics (see *American Journal of Bioethics*, 5(2), 2005). Its reasons for asserting autonomy were the same as those that underlie the "neuroscientific turn," namely, the existence of an "intimate connection" between brain and behavior, the "peculiar relationship between our brains and ourselves," and "the intuition that our ever-increasing understanding of the brain mechanisms underlying diverse behaviors has unique and potentially dramatic implications for our perspective on ethics and social justice" (Roskies 2002, p. 21). Neuroethicists affirm that the neurosciences will redefine "our sense of selfhood and brain-body relations" (Wolpe 2002, p. 8), metamorphose ancient philosophical questions about personhood, and give rise to new moral and legal challenges (Illes and Racine 2005). Given "the capacity of imaging technology to animate mind-brain relationships in ways that compel us to reexamine concepts of identity, personal responsibility, and criminal culpability," neuroimaging turns out to be "a logical focus" of neuroethical inquiry (Kulynych 2002, p. 345). Beyond the connection of brain and personal identity, the case for "neuro exceptionalism" is bolstered by futuristic claims about the unique problems that, according to neuroethicists, functional neuroimaging will raise (see counterarguments in Schick 2005).

The special relationship between neuroethics and functional neuroimaging derives precisely from the latter's capacity to measure brain activity during the performance of an experimental task. The title of an early programmatic article highlights the extent to which neuroethics exists "in a new era of neuroimaging" (Illes 2003); that of another, "from neuroimaging to neuroethics," underlines the origins of the new discipline in the applications of functional imaging (Illes et al. 2003). A 2010 article on possible approaches to revising the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) asked, "What happens if dramatic technical breakthroughs in genetics, imaging or neuroscience cast the problems of psychiatric nosology in an entirely new light?" (Kendler and First 2010). In spite of many caveats and open questions about the nosological and clinical relevance of neuroimaging, the question epitomizes one of the expectations that justify neuroethics: neuroimaging *will* have a significant impact on diagnosis and treatment (Malhi and Lagopoulos 2008; Farah and Gillihan 2012).

In addition to hundreds of articles, the seven neuroethics multiauthored volumes (one handbook, three anthologies, and two collections of new essays) published between 2006 and 2012 confirm the special position of functional neuroimaging in the neuroethical landscape (Illes 2006; Glannon 2007; Giordano and Gordijn 2010; Farah 2010a; Illes and Sahakian 2011; Chatterjee and Farah 2013). In sum, to a very large extent, the existence of neuroethics as a research program with normative aspirations derives from and depends on the expanding application range of functional neuroimaging, coupled with the assumption that "imaging the brain provides information about the mind" (Farah 2010b, p. 4).

Illustrating, Mapping, and Imaging

As far as fMRI is concerned, the assertion that "imaging the brain provides information about the mind" implies that correlations between cerebral activity and the realization of an experimental task during scanning indeed capture a significant relationship between physical brain states and subjective mental states. During the control and experimental conditions, fMRI measures BOLD ("blood-oxygen level-dependent") signals (a hemodynamic proxy of neuronal activity), which are then subtracted from each other; the difference defines the correlation between neural activity and the function which the experimental task is supposed to involve. This neural correlation, usually presented as the "activation" of a brain area, embodies the "information" imaging provides about the mind.

The subtraction method and what that "information" amounts to have long been in dispute (Van Orden and Paap 1997; Kosslyn 1999; Hardcastle and Stewart 2002; Coltheart 2006; Roskies 2009, 2010). It is nonetheless common to say that the "activated" areas "underlie" or "underpin" the functions being studied (Schleim and Roiser 2009). Thus, even though fMRI results are correlations, they are generally discussed in terms that strongly suggest causality (Vidal and Ortega 2011), and this is also part of the "information" imaging is believed to furnish. The colored portions in scans, which are only graphic renderings of correlational results, are widely

perceived as displaying the brain areas that become active during the experimental tasks and sustain the function being investigated.

The methods whereby fMRI images are produced, the information they provide, and the expectations they generate dictate their place in the history of representations of the brain (Clarke and Dewhurst [1972] 1996; Larink 2011). These representations, which have been integral to the production of knowledge about the brain (Mandressi 2011), can be divided into three classes: images that realistically depict morphology, images that show localization of function in anatomical structure, and images that result from records of function.

Descriptive anatomy, which is mostly based on dissection, is accompanied by images of the first class, which may be called "illustrations." Examples are innumerable, but since this class is historically the earliest, it is fitting to mention an early case: Christopher Wren's superb etchings of Thomas Willis' *Cerebri anatome* (1664). Wren's images look realistic; however, they are not like photographs of a dissected brain, but synthesize observations made on different brains (Flis 2012). Their accuracy and the quality of the knowledge they convey contribute to explain why they are considered epoch-making. However, when Willis (1621–1675), a major figure in the history of neuroanatomy (Molnár 2004; Zimmer 2004), dealt with the physiology of mind, he adhered to Galenic humoralism, which, unrelated to neuroscientific research, dominated medical thought until the eighteenth century (Temkin 1973).

According to Galenism, as the blood passes through the organs of the body, it is transformed into subtile fluids or "spirits." It first becomes a "natural spirit" responsible for nutrition and growth. In the heart, the natural spirit mixes with air from the lungs and turns into the "vital spirit" on which motor and vital functions depend. A final transformation takes place in the cerebral ventricles with the formation of the "animal spirits" necessary for sensitive and intellectual functions. The animal spirits were believed to reside in and move among the brain ventricles, which thus constituted the seat of mental faculties. From front to back of the head, these were the "common sense," the imagination and fantasy, the judgment and intellect, and memory (Harvey 1975; Kemp 1990). This "cell doctrine" was the object of numerous illustrations in the medieval and early modern periods. Willis studied the solid parts of the brain. At the same time, however, he linked the imagination to an "undulation" of the spirits from the center of the brain towards its circumference and speculatively placed its seat in the corpus callosum; he made memory depend on the movement of the spirits from the periphery towards the center of the brain and located it in the cortex; and he situated sensory coordination in the corpus striatum, which received the impressions going towards the brain and was, he conjectured, the path by which the animal spirits descended towards the extremities.

A second class of brain images shows functions as localized in anatomical structure; they are constructed by mapping anatomo-clinical or experimental results onto an anatomical picture. Such morphological "mappings," as they may be called, began developing in the eighteenth century. Brain research between the late seventeenth and early nineteenth century was closely connected to investigations of the structure and function of the sense organs. Since the nerves united the soul

and the body, as well as the external world and the brain, the nervous system became in the Enlightenment the common ontological matrix of the sciences of the body and the sciences of the soul (Figlio 1975; Rousseau 2007; Vidal 2011). Throughout the eighteenth century, anatomical knowledge of the brain advanced through surgical practice and pathological and microscopic studies following vivisection or unintended lesions, new dissection, fixation and staining methods, and, starting in mid-century, electrical stimulation experiments (Barbara 2008).

The early decades of the nineteenth century saw the spread of phrenology (Clarke and Jacyna 1987; Renneville 2000; van Wyhe 2002). Based on the theories of the Viennese physician Franz Joseph Gall (1758–1828), who called it "organology" and "doctrine of the skull," it assumed that the brain is the organ of the mind, that each faculty has its own brain "organ," that the size of each organ is proportional to the strength of the corresponding faculty, that the brain is shaped by their differential growth, and finally, that since the skull owes its form to the underlying brain, its "bumps" reveal individual aptitudes and tendencies. Phrenology, and the accompanying practices of cranioscopy and cranial palpation, remained hugely popular into the 1840s, and phrenological publications appeared steadily until after World War I. The typical picture shows a head with neatly delimited zones marked on it, often resulting in a grid, each corresponding to a faculty of the mind.

In the same period, experimental psychophysiology and pathological anatomy gave impulse to the project of localizing mind in the brain (Star 1989; Finger 1994). While phrenology correlated dispositions with cranial shape, the anatomo-clinical method searched for correspondences between symptoms and brain lesions. The advocates of situating mental faculties in discrete loci and those who insisted on the unity of intelligence and the integrated nature of brain action shared such methodological orientation. The case of "Tan," an aphasic patient studied by the French anatomist and physical anthropologist Paul Broca (1824–1880), is paradigmatic of mid-nineteenth-century localization debates. Tan's clinical history and the postmortem study of his brain led Broca to conclude that the faculty of articulate language was possibly located in the second or third frontal convolution. In his foundational "Remarques sur le siége de la faculté du langage articulé," Broca (1861) identified correspondences between mental functions and brain areas. He localized the higher "brain faculties," including judgment, reflection, and abstraction, in the frontal lobes, and the feelings and passions in the temporal, parietal, and occipital lobes.

For nineteenth-century British and German brain scientists, the method of correlating clinical and pathological phenomena was suspiciously reminiscent of the craniological approach (Young 1990). Few, however, would have denied that the extraordinary positive or negative qualities of geniuses, criminals, and the mentally ill were somehow inscribed in the brain. This brand of localizationism matched the nineteenth-century development of anthropometry and the related elaboration of physiognomic, cranial, and bodily typologies (Hagner 2004; Rafter 2008).

Beyond national differences, to know the brain was to know what its parts did and were responsible for. By the late nineteenth century, cerebral localization, differentiation of function, and the correlation of structure and function had become investigative principles; the physiological and functional study of discrete regions of the cortex (mainly by means of lesions and electrical stimulation) resulted in detailed anatomical cortical maps. In the twentieth century, clinical and experimental methods came increasingly together. For instance, as a neurosurgeon treating epileptics with open-skull surgery, Wilder Penfield (1891–1976) stimulated sections of the cortex. On the basis of patients' responses, he mapped areas corresponding to motor and sensory functions and represented them as a "homunculus" whose features are drawn proportionally to the associated brain areas (Penfield and Boldrey 1937; Penfield and Rasmussen 1950; Pogliano 2012). Although the homunculus does not look like a brain and is not topographically accurate, it belongs to the same class of images as those drawn by the neurologist and neurosurgeon Otfrid Foerster (1873–1941), with whom Penfield studied and collaborated, which map sensorimotor regions discovered by means of accidental or experimental lesions onto a schematic but realistic depiction of the cortex.

Illustrations and mappings differ from what might be called "imagings," which consist of tracings derived from recording in vivo processes. The best known is electroencephalography, but starting in the 1860s, the earliest methods attempted to measure and graphically record regional head or brain temperatures, as well as the amount of blood circulating in the brain, and to correlate them with cognitive tasks; research in the 1890s established relations between cerebral functional activity, energy metabolism, and blood flow (Zago et al. 2012). The term *imaging* suits these different visualization techniques, since the progressive aspect indicated by the *-ing* form denotes an ongoing action.

In the early twentieth century, self-recording instruments for graphically registering physiological activity gave rise to the hope of establishing psychological processes as physical facts and of generating a "brainscript" from which to read psychic phenomena directly (Borck 2005). In the 1930s, although electroencephalography inventor Hans Berger (1873–1941) conceptualized EEG "as a device for documenting psychic processes via their physiological correlates" (Borck 2001, p. 583), the technique was celebrated as a mind-reading device. Later digitization has not fundamentally altered the hopes and the issues connected to imaging. Instead, like earlier technologies, functional neuroimaging has been widely associated with mind reading.

The form of localization which functional imaging produces does not consist of establishing the "seat" of particular functions but of showing areas and circuits somehow involved in those functions. Neuroimaging thus collapses the distinction between morphological and functional images and acts as a sort of inward physiognomy (Hagner 2009). Essential for neuroethical considerations is the fact that, even when they look like the realistic reproductions of an entire brain or of traditional brain sections, fMRI images neither apply optical principles nor reproduce anything: they are "belief-opaque in a way photography is not" (Roskies 2007, p. 871). Their appearance embodies decisions about how to generate, process, and

represent numerical data recorded from a functioning brain; this data could be given the form of graphs or curves rather than vibrantly colored brains.

Insofar as fMRI brings to light functional integration, it replaces the static localizationism of mappings with the dynamic localizationism of imaging. From the historical and epistemological viewpoints, it is nevertheless significant that the basic beliefs and hopes associated with functional neuroimaging as well as many of the uses to which it has been put have led to comparisons with phrenology (Uttal 2001) and that phrenology and neuroimaging have been said to share misguided structure-function mapping strategies (Poldrack 2010).

The parallels between phrenology and neuroimaging also evince neuroethical concerns (Tovino 2007b, part V). Both moved rapidly from clinical and research contexts to the public arena, especially law and education, as well as to commercial applications in personal decision-making and employment screening. The issues they raise are related to localization, but not specifically to *functional* neuroimaging. While phrenology professed to identify the cerebral seat of particular functions and anatomo-pathology actually enabled their localization, functional imaging generates correlations between cerebral activity and the performance of a mental task. Yet, although neuroethicists and neuroscientists tend to believe that thanks to fMRI the mind/brain sciences "have made more progress in a decade than had been made in over two thousand years" (Cowey 2001, p. 254), the new functional visualization techniques coexist with old psychological parameters (Hagner and Borck 2001, p. 508) as well as with traditional formulations of the moral and philosophical problems which those techniques allegedly revolutionize.

The Structural and the Functional

As seen above, neuroimaging is part and parcel of the "neuro exceptionalism" that legitimizes the autonomy of neuroethics. This does not mean that all major neuroethical topics are inherently connected to neuroimaging. In the case of the pharmacological enhancement of normal neurocognitive functions, fMRI is sometimes used, but effects are typically assessed with controlled clinical trials comparing the experimental drug with placebo (Repantis et al. 2010). The related neuroethical discussion focuses on classical bioethical issues, such as safety, freedom, fairness, and regulation (Farah et al. 2004; Glannon 2008; Illes and Sahakian 2011; Chatterjee and Farah 2013).

The same applies to some of the central neuroethical topics that are directly connected to brain imaging. First example is incidental findings (Detre and Bockow 2013). Such findings are common in human subject research. In neuroimaging studies, where they display a relatively high prevalence of 2–3 % in neurologically asymptomatic people, they may reveal potentially symptomatic or treatable conditions as well as various markers of cerebrovascular disease (Morris et al. 2009). Reporting them may lead to life-saving care; however, since neuroimaging research often involves scans which are not clinical grade and which may be read by researchers with no training in diagnostic interpretation, suspicious findings may

turn out to be false positives. Such a situation involves dilemmas qualitatively identical to those that arise in bioethics. What makes incidental findings in neuroimaging research a particularly significant topic for neuroethics is that brain anomalies may threaten "the continued function of the individual" (Wolf 2011, p. 626).

Second example is privacy rights. Here again, neuroimaging occupies a prominent place. Its implications offer analogies to those of HIV test results and genetic information, which in many legal systems are subject to heightened confidentiality protection measures. Here too the *neuro* lacks specificity. Moreover, there would be no reason to apply extraordinary measures to data which, though obtained by way of imaging, chiefly corroborates otherwise diagnosed conditions or even provides "correlates" of such psychiatric disorders as depression or schizophrenia. Neuro-exceptional measures could be defended – but that would require accepting that fMRI has the "potential to reveal insights about an individual's thoughts, feelings, preferences, prejudices, and other social characteristics and behaviors" (Tovino 2007a, p. 487).

Third example is neuroscience and the law (Freeman 2011; Spranger 2012). The issues examined in this context, sometimes under the appellation "neurolaw," include among others neuroimaging lie detection, the admissibility of brain scans in the courts, or their relevance for determining degrees of guilt and assessing responsibility. As in neuroethics at large, discussions are very largely focused on or derived from the forensic uses of brain imaging (Simpson 2012a). They typically combine calls for caution concerning real-world applications of neuroimaging with the conviction that, as it becomes "more reliable, standardized, and informative, attempts to use its results in civil and criminal proceedings of all types will increase dramatically" (Simpson 2012b, pp. xv–xvi). In fact, there is no agreement on whether or not neuroimaging will affect legal arguments about free will or undermine agency and responsibility (Aggarwal 2009).

As stated above, neuroimaging collapses the distinction between morphological and functional images. Yet, as the examples of incidental findings, privacy rights, and neuroscience and the law demonstrate, neuroethics relates most specifically to perceptions about the impact of its *functional* capabilities. These, however, have fallen short of their promise. For example, since the introduction of computerized tomography (CT) in the early 1970s, structural neuroimaging has helped to identify pathological lesions in epileptic patients. In contrast, functional imaging has yielded results of very limited clinical significance, "despite many research efforts and massive funding" as well as claims about its potential to localize function or aid in presurgical localization (Shorvon 2009, pp. 47–48).

In the domain of schizophrenia, despite comparable investments, since the first computerized axial tomographies were performed in the mid-1970s, "no consistent or reliable anatomical or functional alterations have been unequivocally associated with psychosis or schizophrenia and no clinical applications have been developed" (Borgwardt and Fusar-Poli 2012, p. 270). The hopes, however, remain high that combining imaging modalities among themselves and with neurodevelopmental

and genetic data will yield unequivocal anatomical and physiological markers (e.g., Insel 2010; Calhoun and Hugdahl 2012).

In the domain of mood disorders, the most consistent structural neuroimaging finding is white matter hyperintensities in unipolar patients; relatively consistent functional neuroimaging findings include a decreased anterior paralimbic and cortical activity in depressed or bipolar patients. Studies in the area repeatedly affirm that brain imaging will contribute to understanding pathogenesis (Koolschijn et al. 2009). A meta-analytic study, however, concluded that after 25 years of scanning bipolar disorder patients and generating over 7,000 MRIs, the consistent findings are few and "regionally nonspecific" (Kempton et al. 2008).

In spite of the extremely limited substance of the empirical results, their lack of clinical significance, the interpretive difficulties they present, and the many methodological and epistemological problems they raise (Vidal and Ortega 2011), researchers involved in the neuroimaging of psychiatric disorders conclude that "fMRI has emerged as an exciting and pivotal tool that has enabled investigators to probe the mind and anchor their findings within the brain" (Malhi and Lagopoulos 2008, p. 114). Even the most cautious discussions (Farah and Gillihan 2012) consider it merely "premature" to include brain imaging among diagnostic criteria for the most recent Diagnostic and Statistical Manual of Mental Disorders (DSM V). This contrasts with other opinions, which recognize that, on account of the very nature of cerebral functions, imaging "may be an inherently inappropriate technology" to study them (Shorvon 2009, p. 48).

The Practical and the Philosophical: Future Directions

As neuroethicist Martha Farah (2005) pointed out, some neuroethical questions concern the practical implications of neurotechnologies for individuals and society, while others, more philosophical, concern the relationship of mind and brain as well as the material determinants of human behavior. The "practical" are mainly related to neuroenhancement, which raises questions about fairness and equal opportunity, as well as to the uses of neuroimaging, which raise issues of privacy, responsibility, and public policy in domains such as the law, education, and public health. The "philosophical," derived from more basic neuroscience but also largely dependent on neuroimaging, touch on the ways we think about ourselves as persons and moral agents.

Overall, the way neuroethics has been practiced up to the moment this chapter was written corroborates the observation that

> neuro-ethical anxieties [about for instance enhancement, authenticity or free will] have become part of the very problem they seek to address. In inflating the powers of the new brain sciences, [. . .] they have become part of a culture of hype and hope, futurology and fear. Far from opening a space for clear thinking about the issues that confront us today, much neuro-ethics implicitly makes the case for those who live on these expectations, be they researchers in search of grants, corporations in search of investment or popular science writers who thrive on sensationalism to sell their products [. . .]. (Singh and Rose 2006, p. 100)

Similarly, mainstream neuroethical practice confirms that "[a]s much as neuroethicists claim to guard society from neuroscience's abuses, they also guard neuroscience from society's criticisms. This enables neuroscientists to more freely push the boundaries on new technologies, piquing public curiosity and expanding the boundaries of neuroethics" (Conrad and De Vries 2012, p. 320). In no area is this truer than in neuroethicists' handling of neuroimaging.

Hence the following two possible new directions for neuroethics. One would consist of self-reflexively examining its role as expert consultant, linked to its focus on "the practical." To extrapolate from criticisms addressed to bioethics (John 2004, pp. 178, 179), it may be observed that such focus concerns problems that are dictated mainly by North American markets and may be "of little ethical concern in the larger context." The predominant empiricist approach, which seeks to assess dilemmas raised in the field, "distorts ethical inquiry by making us focus on particular cases which may not be those of most ethical importance." While it is meaningful to discuss the impact of imaging technologies on brain privacy, it might be more significant to ask whether it is socially responsible to allocate so many resources to neuroimaging in areas where the technology might be unsuitable for the goals pursued, and where most results have long been, and may be expected to remain of doubtful value.

A new task for neuroethics would consist of examining the beliefs and interests underlying such a situation, in order to explain and eventually question its opportunistic alliance with the neuroimaging-driven turn in psychiatry and the human sciences. For example, in dealing with "the puzzle of neuroimaging and psychiatric diagnosis" (Farah and Gillihan 2012) – namely, that although image-based brain correlates have been documented for most psychiatric disorders, functional imaging plays almost no role in nosology, etiology, and diagnosis – neuroethicists warn against premature applications and inflated claims but expect that future advances will allow imaging to play a key role in those areas. An alternative would be to place their "expectational discourses" (Brosnan 2011) and the *neuro* pursuits they legitimate, in socioeconomic, political, historical, and ethical perspectives (Cooter 2010a, b).

Consequently, a second possible new direction for neuroethics would include rethinking its approach to "the philosophical," which has so far embraced an exalted assessment of the potentialities of neuroimaging. The editorial to the first issue of the journal *Neuroethics* asserted that "[n]euroscientific knowledge promises to transform our understanding of [. . .] what it means to be a thinking being" and explained that, whereas medical advances "deal with our bodies, neuroscientific discoveries promise – or threaten – to reveal the structure and functioning of our minds, and, therefore, of our souls" (Levy 2008, p. 2). The "knowledge" and the "discoveries" alluded to are largely attributed to neuroimaging. Since such claims are the cornerstone of neuroethics, the discipline has taken them for granted, rather than dealing with them in their proper contexts.

Historically, however, the notion that, as persons, humans are essentially their brains, dates at the earliest from the late seventeenth century and goes hand in hand with "possessive individualism" and an understanding of personhood that emphasizes individual autonomy; contrary to what neuroethicists seem to believe, it does not result from neuroscientific advances but predates them and has contributed to

motivate brain research (Vidal 2009). History, which is absent from neuroethical inquiry except in the most cursory manner, suggests that trying to understand personhood by showing that there is an autonomous person network in the brain (Farah and Heberlein 2007) is both scientifically and philosophically unpromising. Similarly, sociological research into individuals' uses of "neuro" discourses (O'Connor and Joffe 2013) considerably undermines neuroethics' understanding of neuroscience's social "impact." Finally, a rich literature about the emergence of the brain as icon of Western modernity mediated by imaging technologies (e.g., Dumit 2004; Joyce 2008) problematizes neuroethicists' belief that "imaging the brain provides information about the mind." The present and future of neuroethics are tied to those of that icon in ways neuroethics itself would benefit from examining.

Abstract

Deep brain stimulation (DBS) is an implanted device allowing to modulate selected brain target sites in individuals' daily life. While it was first tested in the treatment of chronic pain, the main breakthrough was achieved in the treatment of movement disorders. The field of DBS now witnesses an exponential growth in clinical applications and investigations, including diverse psychiatric disorders, behavioral states, neurological orphan diseases, and even enhancement purposes. This leads to fundamental questions on the level of research, clinical and regulatory ethics, which are addressed in this section of the *Handbook of Neuroethics*. This introductory chapter provides an overview of the indications of DBS and the central ethical issues of the burgeoning field.

Introduction

The idea to directly intervene in the brain and specifically modulate the activity of certain brain circuits by a simple button press seemed to be utopian for long. It has now become partly real by the rapidly increasing development and application of deep brain stimulation (DBS). DBS systems use a chest- or abdomen-implanted pulse generator to send electrical pulses via an extension wire running at the side of the neck to an intracerebral lead which contains several electrodes at the brain target site. Chronic stimulation of subcortical structures was first used already in the early 1950s (Hariz et al. 2010). Since this time, ablative surgery and electrical stimulation developed in parallel, with first applications of these procedures in the realm of psychiatry and behavior (and not in movement disorders, as often assumed) (Hariz et al. 2010). The notion of "deep brain stimulation" was coined in the mid-1970s, at that time investigated as a treatment for chronic pain (Hariz et al. 2010, 2013). The lack of clear indications, thoroughly controlled trials, and longer term follow-up led to the fact that DBS was never approved for pain by the U.S. Federal Drug Administration (FDA) (Hariz et al. 2013). In 1987, however, the group of Benabid published a seminal work on chronic electrical stimulation of the thalamus for the treatment of tremor (Benabid et al. 1987). Since this time, and in particular in the last 15 years, the field of DBS has witnessed an exponential growth in clinical applications and investigations (Hariz et al. 2013). This rapid expansion now includes DBS investigations in diverse psychiatric disorders, behavioral states, and neurological orphan diseases (Table 34.1), and partly builds on only serendipitous and controversial findings and uncontrolled small case studies. This leads to fundamental questions on the level of research, clinical and regulatory ethics, which are addressed in this section of the Handbook of Neuroethics. The purpose of this introductory chapter is to provide an overview of the indications of DBS, the central ethical issues, and the main perspectives of the following sub-chapters.

DBS in Movement Disorders

In the two decades following the seminal work of Benabid's group on DBS for tremor in 1987 (Benabid et al. 1987), DBS has become a well-established and FDA-approved treatment for three classes of movement disorders: Parkinson's disease (PD), primary dystonia, and essential tremor. In these indications, DBS targets various areas in the basal ganglia and thalamus, including the subthalamic nucleus (STN), the globus pallidus internus (GPi), or different parts of the thalamus (e.g., the ventro-intermediate nucleus [VIM]) (Hariz et al. 2013). Although movement disorders and especially PD will certainly remain the main indication for DBS for the foreseeable future, there are still unsettled issues (Clausen 2010). For example, it is still controversially debated if and to what extent the DBS-induced improvements in the motor domain are also paralleled by an overall improvement in quality of life (Agid et al. 2006; Schupbach et al. 2006). Moreover, the psychiatric effects of DBS in

PD and the effects upon selfhood still warrant a thorough discussion, as outlined in the contribution by ***Paul Foley***. Other authors have shown that DBS ethics does not require any specific ethical criteria, but should follow the widely established bioethical criteria of beneficence, non-maleficence, respect for autonomy and distributive justice (Clausen 2009, 2010; Synofzik and Schlaepfer 2008, 2010, 2011). Foley now applies these criteria to DBS for PD, which serves as a paradigmatic disease for the neuroethical analysis of DBS in movement disorders.

DBS in Psychiatric Diseases

In contrast to widespread assumptions, the renaissance of DBS in surgical treatment of psychiatric illness in 1999 had little to do with nonmotor effects of subthalamic nucleus DBS in PD or with the success of DBS for movement disorders in general (Hariz et al. 2010). Instead, high-frequency DBS for psychiatric diseases took advantage of the experiences of previous psychiatric ablative surgery, in particular using the same brain targets (Hariz et al. 2010). For example, the first modern reports of DBS for obsessive compulsive disorder (OCD) or Gilles de la Tourette syndrome (GTS) aimed at stimulating those targets previously subjected to ablative surgery: the anterior capsule for OCD and medial thalamic structures for GTS (Hariz et al. 2013).

DBS is now (re-)introduced as a treatment modality for various psychiatric and behavioral conditions which not only include OCD and GTS, but also major depression, eating disorders (anorexia nervosa and obesity), aggressiveness/violence, substance addiction, or Alzheimer's dementia. The variety of DBS brain targets tested for each of these diseases is much larger than in DBS for movement disorders. For example, DBS has been tried in nine brain targets for GTS, eight for OCD, and ten for depression (Hariz et al. 2013). The rationale for choosing one particular brain target, but not another, is not always completely coherent. It results from serendipity, theoretical models of the respective brain circuits, brain imaging data (either functional or tractography), previous ablative surgery results, surgeons' and/or psychiatrists' preferences, or on various combinations of the above (Hariz et al. 2013).

It has been cautioned not to prematurely follow an implicit dualism between psychiatric and neurological diseases in the discussion of DBS ethics (Synofzik and Clausen 2011). There are no a priori ethical differences between psychiatric and neurological diseases, and both types of diseases should be analyzed by means of the same bioethical criteria and claims about alleged ethical implications of DBS need to be corroborated by clear empirical evidence in both types of diseases and for each disease specifically. Thus, statements about presumed ethical implications of DBS for a certain psychiatric disease (as well as for a certain neurological disease) require a detailed empirical inquiry. For example, it has to be tested for each disease, whether the respective subject group has sufficient understanding of the risks associated with DBS, has realistic expectations of the likelihood of personal benefit, and can appropriately distinguish between DBS research and routine clinical care (Dunn et al. 2011; Synofzik and Clausen 2011). ***Paul P. Christopher*** and ***Laura B. Dunn*** show that the vast majority of prospective DBS participants with treatment-resistant

depression do have adequate decisional capacity, yet many individuals fail to recognize key difference between DBS research and clinical treatment, a phenomenon known as therapeutic misconception. This phenomenon is probably not restricted to patients with depression, but is likely true for many subjects and diseases where DBS is investigated still on a research basis. In fact, the therapeutic misconception might apply even to surrogate decision-makers as well. Their decision is required in DBS for subjects with Alzheimer's Disease who are increasingly impaired in their decisional capacity, but nevertheless enrolled in DBS trials.

Ethics of DBS Regulation

None of the DBS procedures for neuropsychiatric diseases can already be considered to be "established" (Hariz et al. 2013). In fact, the FDA's recent approval of DBS for OCD as a Humanitarian Device Exemption (HDE) has even been criticized as it removes the requirement for a clinical trial of appropriate size and statistical power (Fins et al. 2011). In contrast to the conventional Investigational Device Exemptions (IDE), where both safety and efficacy have to be demonstrated via properly powered clinical trials, HDEs operate via a lower standard of evidence for safety and do not require strict clinical trials for demonstrating efficacy for approval. Thus, as noted by J. Fins and other prominent colleagues in the field of DBS (Fins et al. 2011), by bypassing the rigors of such trials, premature HDEs for neuropsychiatric DBS put patients at risk, limit opportunities for scientific discovery, and give device manufacturers unique marketing opportunities (Fins et al. 2011). As argued by ***Joseph J. Fins***, the HDE for DBS in OCD is an example of regulatory insufficiency and of the failure to distinguish research from therapy due to the aforementioned therapeutic misconception. He points out that the lower standards of HDEs are meant to facilitate approval of devices that are intended for orphan markets where the disease condition annually affects 4,000 or fewer patients. Since numbers are even lower in rare movement disorders, the same regulatory problem will likely arise not only in the field of neuropsychiatric DBS, but also in the rapidly increasing field of DBS for rare movement disorders like Huntington's Disease, chorea acanthocytosis, dystonia-parkinsonism syndromes, or neurodegeneration with brain iron accumulation (NBIA) (Table 34.1).

Joseph J. Fins demonstrates that DBS devices cannot simply be regulated by methods derived from the regulation of drugs, without a thorough appreciation that devices are different from drugs. Instead, devices require their own ethical and regulatory framework. This framework has to take into account also the context of their use as well as the fact that the manner of a device's approval has implications for therapy and research.

DBS Research Ethics

Serendipitous discoveries and advances in neuroimaging are providing abundant new DBS brain targets for a rapidly increasing number of diverse neurological,

psychiatric, behavioral, and cognitive conditions (Hariz et al. 2013). For example, a case report of DBS of the lateral hypothalamus in an obese patient showed no effect on obesity, but provoked in that patient memory flashbacks (Hamani et al. 2008), which now sparked a trial of DBS for Alzheimer's disease (Laxton et al. 2010). But what happened to all the other single-case DBS interventions for which the primary outcomes were not achieved and no interesting secondary effects were observed? (Schlaepfer and Fins 2010) And is it really justified to launch a cohort study in patients with a severe inherently progressive neurodegenerative disease where subjects will ultimately lose all their cognitive capacities and mobility just based on the "side-effects" of DBS in a subject with a completely different condition?

Many findings in the field of neuropsychiatric DBS (though not in the field of DBS for PD, essential tremor or primary dystonia) rely on single cases or small cohorts, variable methodologies, and differing outcome measures. As argued by ***Matthis Synofzik***, these problems make this field particularly prone to bias and selective reporting, evoke ethical concerns regarding possibly premature expansions to new conditions without appropriate justification and research, and indicate the possibility that media, the public, and institutional review boards might be easily misguided by some reports. He suggests three approaches how these problems might be reduced: by an optimization of trial designs, the implementation of standards of reporting, and the creation of a DBS study register which includes in particular single-case studies or case series.

Intrinsic Ethical Objections Against DBS for Neuropsychiatric Diseases and Enhancement Purposes: Are They Valid?

DBS for neuropsychiatric diseases has been confronted with several ethical concerns which mainly focus on the past uses of psychosurgery, the invasiveness of DBS, and the risks for autonomy and identity. These concerns lead to intrinsic objections against DBS and are deeply rooted in many people's intuitions and frame current ethical discussions. ***Anna Pacholczyk*** scrutinizes these objections, demonstrating that they are mostly not convincing if examined in more detail. They are mainly "rhetorical evocations" and may confound a transparent and conclusive ethical assessment of neuropsychiatric DBS.

The same is true for intrinsic objections against an enhancement use of DBS. The prospects of enhancing memory states (Hamani et al. 2008) and of inducing happiness by a button press (Synofzik et al. 2012) indicate that DBS might serve as an attractive tool not only in disease, but also in healthy subjects in the future (Synofzik and Schlaepfer 2008). But is it ethically legitimate to use DBS even in healthy subjects and for enhancement purposes? Anna Pacholczyk convincingly argues that, for drawing normative arguments to answer this question, it is not helpful to resort to the treatment-enhancement distinction. Instead, the ethical analysis has to be guided by the benefit-harm ratio of DBS enhancement to a particular individual. This implies that DBS enhancement uses cannot be ethically discounted a priori, but warrant a careful consideration of the exact benefit and harm.

Conclusion and Future Directions

There are no convincing intrinsic ethical objections against the use of DBS in neurological or psychiatric diseases – and not even for enhancement purposes in healthy subjects. However, to justify the spread of DBS to larger subject cohorts and novel indications, more empirical research is warranted to provide detailed information on several crucial ethical issues. In particular, it has to be shown for each disease condition that subjects or their surrogate decision-makers have sufficient understanding of the risks associated with DBS, have realistic expectations of the likelihood of personal benefit, and can appropriately distinguish between DBS research and routine clinical care, thus preventing a therapeutic misconception. Moreover, the expansion of DBS needs to be accompanied by the establishment of a novel regulatory framework, which focuses on devices, not on merely adapting drug regulatory policies. Finally, a thorough DBS research ethics needs to developed and uniformly implemented into research, publication, and institutional policies.

Deep Brain Stimulation for Parkinson's Disease: Historical and Neuroethical Aspects

Abstract

The introduction of deep brain stimulation for movement disorders has raised concerns about the impact of therapy upon the personal identity of the patients. It is argued that, while caution is naturally advisable, these concerns have been somewhat exaggerated, and that the ethical approach to the therapy of movement aims to maximize both the motor and psychiatric benefits for the patient, as it is their personal welfare that must be placed at the center of questions of therapy and investigation. The historical development of DBS techniques as applied to the therapy of Parkinson's disease is explored, including their status as less destructive and partially reversible successors to surgical techniques employed in the pre-L-DOPA era.

Introduction: Historical Development

Neurotransplantation naturally involves neurosurgery, but deep brain stimulation (DBS) represents the more direct successor to the ablative surgical approaches to the relief of Parkinson's disease (PD) developed prior to the introduction of L-DOPA therapy. Unlike the therapies discussed in ▶ Chap. 29, "Parkinson's Disease and Movement Disorders: Historical and Ethical Perspectives," the primary target is not modulation of dopaminergic transmission, and the mechanisms underlying its efficacy remain unclear (Benabid et al. 2009; Miocinovic et al. 2013); nevertheless, the major final site of action is presumed to be, as with dopaminergic therapies, the striatum, and DBS alleviates the same symptoms as L-DOPA, and to the same degree (apart from postural instability, where L-DOPA is superior). Hopes that DBS may slow disease progression via neuroprotection of surviving nigral cells (see, for instance, Spieles-Engemann et al. 2010) have not yet been confirmed in patients; there is some evidence that its benefits, like those of DRT, decline with time (Fasano et al. 2010). Although earlier applications of DBS approaches are recorded, including to the therapy of movement disorders (reviewed: Stahnisch 2008; Hariz et al. 2010), these predecessors have had at best very limited influence upon the development of contemporary DBS, which was introduced as a reversible form of neuro-ablation.

Ablative surgical interventions had been undertaken since the early twentieth century, but only where the "*abject condition of the sufferer and his forlorn life-outlook*" (Meyers 1942) justified the radical procedures involved. Until the mid-1950s, ganglionectomy and other lesions of the pyramidal tracts aimed to control tremor and rigidity; various lesions of the cerebral cortex were also tried, but the ensuing functional losses dissuaded against widespread application (reviewed: Cooper 1961). Russell Meyers experimented with various lesions of the basal ganglia, favoring sectioning of pallidofugal fibers, but the fatality rate of this difficult operation was high (greater than 15 %; other surgeons reported fatality rates of up to 41 %); most neurosurgeons preferred a more direct attack upon the pallidum to relieve rigidity (death rate: 7.5 %).

The adoption of stereotactic surgery in the early 1950s permitted more precise procedures and thus further reduced the risks of the intervention. In 1953, Rolf Hassler and T. Riechert introduced thalamotomy into the surgery of PD on the basis that pallidofugal fibers travel to thalamic nuclei, which in turn projected to the motor cortex. By the late 1950s, lesioning of the ventral intermediate/ventrolateral nuclei had displaced pallidotomy as "*the single most effective lesion for producing complete and enduring relief of parkinsonian tremor and rigidity*" (Cooper, cited by Redfern 1989). Although only 15 % of patients were suitable candidates for such interventions, 90 % of this select group could expect relief from tremor and rigidity (but not akinesia), and stereotactic techniques had reduced the rate of serious complications to about 10 %, and mortality to less than 1 %. The often spectacular abolition of tremor achieved with thalamotomy was not always permanent, with reports of recurrence in 4–20 % of patients; this could be reduced by increasing the lesion size, but only at the cost of temporary (25 %) or permanent (2–9 %) adverse

effects, including motor deficits, dystonia, and speech and sensory disturbances. Bilateral thalamotomy was rare, as it was associated with profound neuropsychological side effects.

Lesioning of the subthalamic nucleus (STN) was introduced in the early 1960s, but the unprecedented effectiveness of the newly introduced L-DOPA therapy threatened to render surgery obsolete for all but the most hopeless cases. Thalamotomy was revived in the 1970s for patients with L-DOPA-unresponsive tremor, while Laitinen and colleagues resumed operations on the medial pallidum in 1985 (detailed reviews of history of PD surgery: Redfern 1989; Benabid et al. 2009; for review of surgery for movement disorders: Krauss and Grossman 2002).

Location of the site to be lesioned was difficult prior to the availability of neuroimaging. Deep brain electrophysiological recording was employed to identify the target region or regions to be avoided (such as the sensory thalamus) according to their characteristic firing patterns; an alternative was electrical stimulation, which could also identify pyramidal tracts. It was in this latter mode that the Grenoble neurosurgeon and professor of biophysics Alim-Louis Benabid and Pierre Pollak, exploring the effects of different pulse frequencies, discovered in 1987 that high frequency stimulation ($\geq$100 Hz) immediately and reversibly abolished parkinsonian tremor (see also Benabid et al. 1991, 2009). This phenomenon had been noted in experimental microelectrode investigations in humans as early as the 1950s (Blomstedt and Hariz 2010), but its therapeutic potential had not been exploited for technical reasons. The opportune discovery echoed Penfield's mapping of the cerebral cortex by stimulation of patients' cortices, to which he had access for unrelated medical reasons: Benabid noted that he stumbled upon the tremor-suppressant effect of high frequencies during a thalamotomy simply because he was curious about what would happen if he varied the stimulus frequency. He was, however, prepared for the discovery, commenting that he had mused beforehand over the different problems associated with L-DOPA therapy and the surgical treatment of PD (Williams 2010).

The first implantation of a permanent electrode, in the ventral intermediate nucleus (Vim) of the thalamus, was undertaken on an explicitly experimental basis, with the subject's consent; the patient had already undergone unilateral thalamotomy, and had for some time sought to have the other thalamus lesioned. The results encouraged a pilot project in patients for whom a second thalamotomy was indicated, again with explicit consent, and again with success, leading to its application in other conditions in which thalamotomy was also employed (dystonia, multiple sclerosis tremor). Seven years after the first implant, the authors regarded the effectiveness, safety, sustained benefit, and absence of serious side effects as recommending its adoption in place of surgical ablation, particularly where bilateral thalamotomy was indicated. The final breakthrough was achieved in 1993 by changing the target to another site, less used in ablative surgery because of the difficult access: the subthalamic nucleus (STN) (Benabid et al. 1993, 1996).

Interest in surgical solutions was promoted at this time by advances in technology, such as neuroimaging, but more so by the development of detailed models of basal ganglia organization and function, based upon extensive animal studies,

particularly of the MPTP model of PD. In this system, the STN is the major excitatory nucleus of the basal ganglia, projecting to both segments of the pallidum and substantia nigra, amongst other regions, while itself receiving input from cortical and subcortical regions (contemporary overviews: Bergman et al. 1990; Parent 1990). Dopamine replacement therapy (DRT) reduces firing of this nucleus, and the aim of DBS is to achieve this inhibition with greater precision, allowing the reduction of L-DOPA dosage and hence of medication-related dyskinesias and fluctuations. DBS-STN had been found to reduce parkinsonian symptoms in the MPTP monkey model of the disease prior to its trialing in human patients. Surgery thus no longer consisted of the *destruction* of a *location* or *neural pathway* based upon empirical findings in the human brain, but explicitly involved *modulation* of one component, a *system* of neural circuits defined in recent animal experiments. It should be noted, however, that this rationale facilitated acceptance of DBS, but did not underlie its introduction; as Benabid et al. (2009) frankly conceded with respect to the its mechanism: "*How this could work? We don't know, but 'who cares, it works.'*" Further, the neurosurgery theater was no longer the preserve of neurosurgeons, with neurologists and neurophysiologists increasingly involved in planning and monitoring of interventions; as Hariz (2003) noted, few publications on PD neurosurgery now include a neurosurgeon as the primary author. In any case, the precise mechanisms underlying its benefits remain to be clarified (Amadio and Boulis 2011).

DBS requires two separate operations: the first implants two electrodes (1½ mm diameter: size of STN = c. 6 × 3½ × 5 mm) into each side of the brain, using stereotactic and brain imaging techniques to locate the electrodes; the second installs a pulse generator, similar to a heart pacemaker, usually located subcutaneously in the chest. The degree of stimulation by this generator can be continuously controlled within pre-set bounds by the patient. Alternative targets for DBS in PD include the internal pallidum (generally regarded as somewhat less effective than DBS-STN, but with fewer psychiatric side effects; recent review: Odekerken et al. 2013) and the ventral intermediate thalamus (in tremor-dominant PD).

DBS is both a safer and more easily regulated successor to ablative surgical approaches, and there is little doubt that DBS achieves the wished-for amelioration of major motor symptoms – it is, in fact, one of the few surgical procedures supported by evidence from double-blind, randomized trials (class I evidence). It alleviates the same symptoms as L-DOPA, and to the same degree (apart from postural instability, where L-DOPA is superior). Its major benefits is that it permits reduction of L-DOPA dosage, and thus reduces the incidence of L-DOPA-related dyskinesias, as well as the vascular and gastrointestinal effects of DRT; it also relieves anxiety and improves mood in most patients (Weaver et al. 2009; Nazzaro et al. 2011; Ashkan et al. 2013; Schuepbach et al. 2013).

DBS is currently licensed for the therapy of PD, dystonia, and essential tremor, and in PD only as a last resort for patients with long-standing, L-DOPA-responsive PD for whom pharmacological methods are not providing adequate relief ('Core Assessment Program for Surgical Interventional Therapies in Parkinson's Disease' (CAPSIT-PD); Defer et al. 1999). Morgante et al. (2007) found that

maximally 4.5 % of 641 PD patients he had assessed qualified on this basis for DBS, with most excluded by insufficiently severe symptoms. More recently, an expert conference arrived at consensus criteria for DBS that defined suitable candidates as "*patients with PD without significant active cognitive or psychiatric problems who have medically intractable motor fluctuations*, *intractable tremor*, *or intolerance of medication adverse effects*." It was noted that optimal results might be achieved only after 3–6 months, and that DBS-STN could be complicated in some patients by increased depression, apathy, impulsivity, impaired verbal fluency, and executive dysfunction (Bronstein et al. 2011; see also Müller and Christen 2011; Jankovic and Poewe 2012). Despite these restrictions, at least 80,000 movement disorder patients had undergone DBS implantation by early 2010.

The most important immediate risks associated with DBS are those of neurosurgery: the likelihood of hemorrhage (2–4 %) and surgery-related infection (2–6 %) are regarded as acceptable. The most important specific complications include mislocation or breakage of the leads, potentially requiring a second, corrective operation. The overall complication rate has been estimated to be about 7 %, a decline from the figure of 25 % during the first 2 years of the century, indicating that most problems can be reduced through experience and technological advances. One undesirable aspect of the procedure is the fact that brain tissue is irreparably destroyed by the insertion of the leads, the long-term consequences of which are unknown (see, for instance, Burdick et al. 2011). While dementia following DBS for PD has been reported, most authors have detected no evidence of this in their patients; as the prevalence of dementia in PD patients in general is as high as 75 % (Jellinger 2012), the consensus is generally that its development probably reflects disease progression rather than a therapy effect (Amadio and Boulis 2011; Baláž et al. 2011b; Clausen 2011; Williams et al. 2011; Weaver et al. 2012). Voges et al. (2007) found that 0.4–1 % of interventions were followed by death or incapacity within the month.

Psychiatric Effects of DBS for Parkinson's Disease

Although it was not discussed in specifically neuroethical terms until 2011, the non-motor effects of DBS in PD have been recognized for more than a decade, and the discussion of the ethics of DBS predates its application to PD (Hariz 2012). The major ethical issue has concerned potential alterations in personality or identity. As these changes are not observed with DBS for essential tremor (a common, pure motor disorder) and dystonia, as stimulation is applied elsewhere (ventromedial thalamus and pallidum, respectively; for the latter, the patient experience has specifically been described as "*being the same inside*, *yet with a new body*": Hariz et al. 2011), so that they probably reflect the fact that the STN serves "*as a nexus that integrates the motor*, *cognitive*, *and emotional components of behavior*", probably as an indirect modulator of both cortical and subcortical structures (Baláž et al. 2011b; see also Mallet et al. 2007).

The effects of DBS upon mood and personality not only raise of variety of ethical questions for PD therapy, but have partially motivated the use of DBS in a variety of non-motor conditions, including obsessive-compulsive disorders, intransigent depression, addiction, and conduct disorders (reviewed: Holtzheimer and Mayberg 2011; Lyons 2011; Wichmann and Delong 2011; Miocinovic et al. 2013), as well as in consciousness disorders (such as vegetative and minimally conscious states: Sen et al. 2010; Giacino et al. 2012; Yamamoto et al. 2013). In these cases, the collateral mental effects reported in PD therapy are among the major desired responses to treatment, and neuroethical concerns regarding DBS for PD were primarily prompted by this possible expansion of use beyond purely neurologic cases. DBS-mediated modification of personality and mood is, in effect, a more refined approach to managing the relevant disorders than psychopharmacology, and probably accompanied by fewer adverse side effects (Synofzik and Schlaepfer 2011; Synofzik et al. 2012). The question of whether use of this technology by healthy persons for purposes of "neural enhancement" is desirable is a separate issue, and only tangentially relevant to movement disorders.

Witt et al. (2008) found that 16.7 % of DBS patients suffered severe psychiatric side effects (mostly apathy and depression) – as did 12.7 % of PD patients receiving best pharmacological treatment, and in this latter group the rate of psychosis was higher. Hälbig (2010), on the other hand, commented that side effects were often reported in uncontrolled studies with small sample sizes, so that the role played by misplaced electrodes or special patient features cannot be assessed. Schüpbach et al. (2006) documented subtle personality changes in unstructured interviews, finding that several patients were more verbose, irritable, and impatient, and that they expressed their opinions more freely; they therefore recommended such interviews for assessing the impact of DBS on personality in order to detect symptoms missed by standardized tests in larger trials (including acute depression, hypomania, and mirthful laughter or pathological crying; see also Krug et al. 2010; Müller et al. 2010; Witt et al. 2011). In their close analysis of personality changes, Müller and Christen (2011) concluded that the small cognitive declines in executive functions, memory, and verbal learning and fluency had only a minor impact on quality of life, although caution was advised in the case of prospective patients already exhibiting problems in these areas. Apathy and depression, both difficult to quantify, were probably related to PD itself, unmasked by reduced dopaminergic medication. Less quantifiable intellectual, affective, and behavioral effects, in contrast, had a potentially major impact on quality of life: complex mental deficits (anticipation and planning, voluntary attention control, organization of complex thoughts) on the one hand, increased energy, novelty-seeking, and risk-taking on the other – none correlated with motor symptom improvement or pre-treatment personality – may clearly have a positive or negative impact upon the patient, depending on their attitude (and that of their environment) to these changes.

There have been occasional reports of impulse control disorders or aggression following DBS-STN (see Frank et al. 2007; Hälbig 2010; Klaming and Haselager 2010; Müller 2010; Broen et al. 2011; Raja and Bentivoglio 2012), but DBS can

also resolve DRT-related behavioral problems, including pathologic gambling, via reduced medication dosage (Müller 2010; Broen et al. 2011); Lhommée et al. (2012) recently proposed that DBS should be specifically offered to DRT patients experiencing addiction problems, although the risk of initial apathy (which they associated with reduced DRT) needs to be carefully monitored in order to protect the patient from depression and suicidal thoughts. It has also been reported that the addiction problem may eventually recur (Shotbolt et al. 2012).

A certain "satisfaction gap" can initially exist between the objective improvement in motor performance achieved by DBS and the subjective state of the patient: "*the doctor is happy*, *the patient less so*" (Agid et al. 2006), "*a distressed mind in a repaired body*" (Schüpbach et al. 2006; see also Krug 2012). This phenomenon requires further exploration, and perhaps dampening of patients' expectations prior to surgery, although even unhappy patients are generally unwilling to discontinue DBS, and most longer term studies find a significantly improved quality of life; a survey of 100 German patients found a median satisfaction rating of 75 %, while only four patients indicated that they regretted the operation (Müller et al. 2010. See also Alvarez et al. 2005; Dörr 2010; Baláž et al. 2011a; Franzini et al. 2011; Smeding et al. 2011). The feelings of the patient immediately after initiation of DBS should not be over-interpreted; a certain initial trepidation and even alienation is natural in someone who now has a metal case in their chest with which they can alter their brain in a manner they do not completely understand; but as they become accustomed to both its benefits and its possible drawbacks, it is viewed as no more exotic then their many pills or their glasses.

Most dissatisfaction, in fact, stems from the personal and social adjustment required by their increased mobility, and from the recognition that even successful DBS does not restore their lives to full health and prosperity. A syndrome termed the "*burden of normality*" may be involved, the biographical adjustment arising from the fact that abrupt amelioration of a severe illness represents a psychological shock that requires time to be managed; the shock may be all the greater than other life events requiring adjustment because mental processing has improved, opening the patient to greater than previous awareness of their situation (Gilbert 2012). Further, the subjective quality of life is not always as reduced by severe neurologic disease as might be supposed; a high degree of adaptation by the patient to their disorder (the degree of acceptance by post-encephalitic parkinsonism patients for as long as half a century was nothing short of astonishing) means that relief of motor symptoms may not ultimately achieve as much for their sense of well-being as anticipated, let alone provide a panacea for all the ills in their lives. Social factors are evidently also involved: Jabre and Bejjani (2007) commented that Lebanese patients did not appear to suffer the same adjustment difficulties as their Western counterparts. A cynic might, indeed, regard post-DBS melancholia as a First World problem: a technological marvel improves a patient's condition so remarkably that they can be either disappointed or overwhelmed by their good fortune. The patient must in any case be counseled prior to surgery with regard to what can and cannot be expected from DBS, although it is unlikely that many prospective candidates will be dissuaded by the fear of disappointment.

Gießen sociologist Helmut Dubiel (2009) provided an inner view of the changes he experienced in response to DBS. Despite much improved motor performance and reduced L-DOPA dosage – which he consciously registered as positive – he felt during the first year post-surgery that he had merely "*replaced the plague with cholera*": depression, impaired olfactory sensitivity, shortness of breath when bending, loss of postural stability, and a shuffling gait that attracted attention in the street were all regarded as being as bad as the banished symptoms, and speech deficits (reduced speed, low volume, slurred articulation) were particularly upsetting for a professor whose self-worth placed great value on his once impressive speaking voice. Dubiel learned that by reducing stimulation he regained his ability to speak clearly – and his accustomed intellectual vitality was also restored – but he was also immobile and depressed; with increased stimulation he could walk comfortably, but not speak. It is less appropriate to discuss such experiences in terms of "identity," as Baylis (2011) has done, than as the natural adjustment to new circumstances that patients must confront during any form of rehabilitation; in fact, Dubiel's insightful account reveals an unshaken identity, a man with an intact mind, but frustrated by the limitations placed upon him by his still defective body.

The rate of attempted suicide is not much higher in DBS patients (1.35 % according to a meta-analysis, one-third realized) than in the general population, but much higher than that for other PD patients, so that DBS patients should be carefully assessed both prior and subsequent to initiation of treatment (Voon et al. 2008; see also Müller 2010). This is particularly important, as suicide is not always preceded by clear depression, and could, as in encephalitis lethargica (EL), be more the consequence of momentary impulsiveness or of a cool assessment of their situation and their future prospects (Müller and Christen 2011; by way of comparison, cf. Fleck 1933 for discussion of rational and impulsive suicide in EL).

A frequently cited extreme example of the psychiatric effects of DBS is the report of Leentjens et al. (2004). A 62-year-old man developed a manic state following successful DBS for advanced PD, in which state he was assessed as being mentally incompetent; reduction in the level of stimulation, however, also restored the motor disability that rendered him bed-bound. The patient was consulted during his DBS-off phase as to whether he wished to continue DBS and be confined in a psychiatric hospital, or to end treatment and be admitted to a nursing home with his intellect intact; the man chose DBS and motor freedom over mental competence. This choice posed several ethical issues, not the least of which was the responsibility of the physicians for averting not only immediate mental harm (mania), but also potential longer term, perhaps irreversible CNS changes: that is, should they (or a legal guardian) override his short-term autonomy to possibly protect his future autonomy (which they might also block)? For a patient of this age and degree of debility, allowing a free decision concerning their own fate is eminently appropriate, as was decided in this instance.

Such cases are, however, highly unusual; more typical is an improvement by DBS-STN of mood and spontaneity. This may itself cause difficulties: the consequently increased enterprise of the patient may disturb their relationship with a spouse or other carer unwilling to surrender their dominant role, or who

conversely expects a greater assumption of responsibility following motor improvement than the patient feels capable. One overview noted that one in eight couples had divorced within two years of DBS (Müller and Christen 2011; see also Schüpbach et al. 2006). Some patients are also unable to continue their previous employment, either because they feel that it is too demanding, or because they prefer to devote themselves to other activities (Schüpbach et al. 2006; Clausen 2011). Relatives may also be alienated by the sense that the changes in their loved one are associated with a man-made device, triggering associations with "cyborgs" (Müller et al. 2010), but in this situation, it is clearly the relatives that require counseling. It has also been found that aspects of *emotional processing* may be modified by DBS-STN (for example, Péron and Dondaine 2012), and this too will modify the interactions of the patient with their environment.

Changes in personality can ultimately be regarded as positive or negative only with respect to how the patient and those closest to them regard them, with respect to how they promote the patient's ability to pursue and achieve personal goals (cf. Synofzik and Schlaepfer 2008; Clausen 2010). Hälbig (2010) cited a case in which a psychiatrically healthy but rather introverted, cautious patient delighted his family with newfound curiosity, spontaneity, and joyfulness (and increased sexual initiative) following DBS; these changes might very well have been interpreted in another relationship as disruptive or unsettling. Even pathological gambling and similar "negative" outcomes may be extreme forms or expressions of the increased spontaneity and reduced inhibition experienced by many patients as a welcome corollary of therapy (cf. Appel-Cresswell and Stoessl 2011; see also Synofzik and Schlaepfer 2008).

There is no doubt that the improvements wrought by DBS represent a major upheaval for all concerned, and Samuel and Brosnan (2011) have criticized the strict focus on the immediate interests of the patient, arguing that such "principlism" (ethical positions based upon the principles of beneficence, non-maleficence, autonomy, and justice) underestimates the significance of social and cultural factors in medical decision-making: "*principlist bioethics focuses narrowly on the patient as an individual*." The detachment from clinical reality evident in this stance would ultimately deny the ability of the patient to make genuinely informed decisions on health matters, given the manifold societal influences upon such decisions, while also warning against any therapy that might result in changes of the relationship of the patient with his surroundings (which would exclude any strategies with an impact upon CNS function or mobility).

It would be hardly ethical to deny the patient treatment in order to satisfy the wishes of their partners: denial of liberation from the captivity imposed by their condition cannot be justified by concerns that they will use their freedom against the wishes of their loved ones. The feelings of the partners should not be dismissed out of hand, particularly as they have often made sacrifices over many years to assist and support their chronically ill loved ones. Robin Mackenzie (2011) asked whether "*family/carers* [*must*] *look after strangers*?", arguing that DBS patients, in contrast to those who have suffered stroke, brain trauma, or dementia, "*may not behave or feel like familiar damaged or diseased loved ones*, *but like healthy strangers with*

claims on family/carers' time, affection, and assets." The personality changes assumed by Mackenzie – they "*lose their capacities for empathy, insight into their own behavior and considering others' interests*" – are from the extreme end of the range encountered in DBS, but his suggestion that consideration of the potential for such changes be incorporated into pre-surgery informed consent documentation has merit. It should nonetheless be recognized that all personalities inevitably change in the course of a relationship – few spouses would argue that their partner was exactly "the same person" as the one they married years or even decades earlier – and that this cannot be interpreted *a priori* as an imposition or affront, particularly where the bone of contention is that the once passive patient had become an active participant in their own life. Haahr et al. (2013) found in their thoughtful article that solidarity characterized a successful relationship before and after DBS, but that the accent shifted from "*living in partnership*" prior to treatment to either "*a sense of freedom embracing life*" or "*the challenge of changes and constraint*" afterwards.

Respecting the autonomy of the patient entails respect for their informed choice of therapy, even where it may result in changes of which a loved one may not approve. Patients and their families should, in any case, be thoroughly advised prior to therapy of the potential for such changes in order to assist both informed consent, as well as adjustment to any alterations that eventuate.

Effects of Deep Brain Stimulation for Parkinson's Disease upon Selfhood

Some commentators maintain that DBS-STN effects perhaps unpermitted modifications of personality or even of identity, that "*DBS arguably tweaks the organ of personhood*" (Amadio and Boulis 2011). There is, however, no a priori reason for a privileged status of the pre-DBS personality that demands its "preservation": not only has the personality of the patient been shaped throughout life by their personal biography, it has also been affected both by the disease process (directly, and in their psychological response to the experience of parkinsonism) and by medication. There is certainly no "genuine" or "underlying personality" that merits restoration, even were this technically feasible (cf. Synofzik and Schlaepfer 2008).

Those who suspect that DBS may alter selfhood typically employ a *relational account* of identity that does not distinguish clearly between "identity" and "personality": "*My identity is not in my body or in my brain, but in the negotiated spaces between my body and brain, and the bodies and brains of others*" (Baylis 2011). The distinction, however, is crucial to understanding people suffering disorders such as PD: as was most dramatically demonstrated by post-encephalitic parkinsonism, motor deficits and bradyphrenia can severely restrict the expressive aspects of personality while permitting the preservation of the underlying identity (Foley 2012).

Facets of *personality* may be tweaked by DBS – but the identity remains untouched. *Identity* is molded to a large degree by interactions with others and with the material world, but is ultimately an internal experience; *personality*

describes elements of this identity as presented to and experienced by others: the relaxed, jovial person valued by a friend is the unserious buffoon decried by his enemies. Personality is more liable to change than identity, as it involves interactions of the person with the outside world, and may be both consciously and unconsciously modified according to context, always in accordance with the preservation of the identity, which is, in contrast, more stable and less amenable to alteration. Robinson Crusoe retained his identity throughout his sojourn, despite the fact that lack of human interaction meant that his personality was no more discernible than light in a vacuum. This distinction between identity and personality was clear to many observers of the EL behavior syndrome during the 1920s, so that many recognized neither "immorality" nor "character change" in the affected children (see ▶ Chap. 29, "Parkinson's Disease and Movement Disorders: Historical and Ethical Perspectives") but rather an altered relationship of the physical child with the world imposed by subcortical changes.

Although post-DBS changes have been described as a "*unique form of biographical disruption*" (Gisquet 2008), there is no question of any change so dramatic as to justify description as a "change of identity." Dubiel's insightful account also reveals an unshaken identity, a man with an intact mind but frustrated by the limitations placed upon him by his still defective body, despite the improvements conferred by therapy. As Klaming and Haselager (2010) asked, "*the question that we raise here is whether there is reason to believe that DBS can lead to legally relevant discontinuity type of phenomena regarding memories, intentions, beliefs, goals, desires, and similarity of character between the patient in 'DBS-on' and 'DBS-off' conditions*." The cited case of a 65 year old PD patient who developed manic (disinhibition, amorousness) and psychotic (paranoia) symptoms as an example of personal discontinuity does not amount to a change in identity, unless it is supposed that psychiatric patients in general undergo changes in identity rather than mental function. This direction might be philosophically interesting, but in practical terms is fruitless: mental competence and legal responsibility may be altered in rare cases by DBS-STN, but not the underlying identity.

The fear of external "mind control" and the difference from its psychopharmacological correlate were forcibly expressed by Dubiel (2009) with his observation that "*With long-term medication the neurologic patient becomes a zombie, with a pacemaker he becomes Frankenstein's monster*." This pessimistic view was supported by his neurologist discussing the electronic records of his stimulator, for Dubiel a surprising intrusion into his privacy; he felt that such traces might be used for the social control of his device, and of him. While patient perceptions are important, however, his fears are more a reflection of his unusually intense philosophic analysis of his "implantedness"; most patients instead become accustomed to their device without any definite feelings, positive or negative. It should also be noted that the personality-altering aspects of DBS cannot, in most cases, be turned on and off by means of the stimulator, but are rather the results of middle to longer adjustments following activation of the device.

An unusual case of personality dissociation nevertheless merits attention in this regard: A 43 year old man experienced a dramatic personality dissociation twelve

months after commencement of self-adjusted thalamic DBS for refractory Tourette syndrome. If right side stimulation amplitude was increased, *he* "*anxiously crouching in a corner*, *covering his face with his hands*. *He spoke with a childish high-pitched voice and repeatedly insisted that he was not to blame*. *Sentences were brief and grammatically incorrect*. *If approached by one of us*, *he fiercely kicked his feet because he feared being thrown in the basement*." When stimulation was removed, he was amnestic for this alternate state, remembering only a rush of threatening childhood memories. Assessment of cerebral blood flow supported temporal lobe as well as the fronto-limbic disconnection hypotheses of dissociative disorders (although a direct effect upon the thalamus, long regarded as being involved in the production of a proto-consciousness, should not be excluded) (Goethals et al. 2008). It is important to note that the site of stimulation (thalamus) means that this idiosyncratic response – this is the only case thus far reported – cannot be generalized to DBS in PD. On the other hand, it provides a warning to be heeded in the further application of the technique, particularly as the change in consciousness – if this expression accurately describes the phenomenon observed – was easily manipulated, both of ethical concern with regard to the potential for "mind control", but also encouraging in light of the fact that the "old personality" was neither lost nor permanently impaired.

A hypothetical case in the book *Personality*, *identity and fractured selves* (Mathews et al. 2009) involved a PD patient whose apathy was treated in the near future by DBS. Both the motor symptoms and mood of the patient responded well to therapy, but his "personality" had also changed: Not only was he more outgoing and sociable, he was no longer as devoted to his job as previously; he was more interested in pursuing charitable and political causes, the former Republican was now a solid Democrat. It should be noted, however, that this hypothetical case mixes the known psychological effects of DBS (increased sociability and reduced inhibition) with effects not described in the literature (enhanced intelligence); further, treatment of extreme apathy with DBS is not currently undertaken. Such hypotheticals are interesting intellectual exercises, and may assist to anticipate future developments, but they are of only limited value for addressing current, real situations.

"*The ethical discussion on this point is complicated by the lack of clear and undisputed definitions of central concepts such as personality*, *self*, *identity*, *and authenticity*" (Merkel et al. 2007). The detailed discussions of what constitutes "personality" and "self" are appropriate and important, but are irrelevant to DBS for movement disorders: DBS-STN has no impact upon memory or values (significantly, not even in cases of impulse control), and only exceptionally produces changes that could be detected by standard instruments for the diagnosis of clinical personality disorders. Most instances interpreted as examples of alienation – such as the 38 year old woman with genetic PD (she had suffered PD for 30 years) who complained, "*Now I feel like a machine*, *I've lost my passion*. *I don't recognize myself anymore*" (Schüpbach et al. 2006; see also Kraemer 2011) – involve figures of speech rather than essential changes of identity. Witt et al. (2011) took this as the starting point for a discussion of identity and selfhood, disregarding the fact that the

mental condition described by the patient is entirely comparable with other forms of "fuzziness" or "clouded cognition" – or even simple ennui – that would not normally provoke thoughts of altered identity (cf. also Baylis 2011). The real issue is whether the subject perceives a continuity between their selves before and after DBS, and that they have retained their identity is almost by definition established by their assertion, "I am different to how I was before," "I feel other than I did before." It is more apposite (and banal) to recognize that restoration of control of their own body provides both the physical possibility and the motivation to re-assert their interests in the world: "*I am again myself, and I don't put up with as much as I did before. I stand up to my husband more than I used to*" (Müller et al. 2010). If anything, DBS assists the patient to attain a state that they regard as more authentic and autonomous than previously.

Much of the uneasiness with which DBS is regarded by some is elicited by the implantation of a man-made device into the CNS, an approach that causes more disquietude than the use of less controllable psychopharmacological agents to achieve the same ends. Hälbig (2010), for example, wrote that, "*in parallel with a transfer of his control over mind and body to mechanical devices and to the treating physicians, the patient suffered a personality change with a partial loss of his personal autonomy*." Any transfer of control, however, is in favor of the patient: they control the degree of stimulation – they can even turn the device off permanently – and thereby have greater hegemony over the STN than prior to implantation; voluntary hegemony rather than the automatic regulation enjoyed by non-parkinsonian persons, but self-control nonetheless. This may, ironically, change somewhat if anticipated advances in DBS are realized, such as *closed-loop DBS*, in which feedback from brain electrical activity automatically adjusts stimulation. It is even envisioned that "*within the next decade, hundreds if not thousands of submicron-sized monitoring/modulating electrodes can be placed wherever needed to restore brain function to normal. The term "neuromodulation" will likely replace deep brain stimulation (DBS) as both neurochemistry and electrical activity are included in the therapeutic modalities*" (Andrews 2010a, b).

This anticipated move from "jamming" the STN to more sophisticated modulation of CNS function promises more targeted therapy for patients, and may obviate concerns that chronic continuous stimulation might alter CNS neural activity in an undesirable manner (see, for example, Glannon 2010), but will also exacerbate fears of technological brain control. Two factors will be crucial for ensuring the ethical deployment of such devices: firstly, the patient must retain the option to adjust the activity of such devices, at least within defined parameters that maintain its safe function, and even to turn the device off; secondly, the device should not be subject to external control (for instance, by wireless communication with a computer; cf. Sliwa and Benoist 2011) without the express consent of the patient, and then only under strictly defined conditions dictated by the patient's condition. This issue will probably play a greater role in the extrapolation of DBS to mood and behavioral disorders than in the therapy of movement disorders, as well as in ethically even more problematic extensions to "neural

enhancement" or the control of criminal behaviors, roles in which psychopharmacological agents have played prominent roles.

Fears that patient autonomy are undermined by DBS are often paired with the concern that the patient might use this same autonomy to adjust the level of stimulation to achieve what they feel to the best setting for them, rather than relying upon the Professor to make this decision for them, opening the door to "wish fulfilment medicine" and "neuro-enhancement". Should one begrudge PD patients the opportunity to tweak their mood in a manner that renders life more comfortable? (see Hälbig 2010). Should it even be permitted to trade off aspects of one's psychiatric health in order to achieve motor freedom, should one so desire, as in the Leentjen case? It is ironic that neurologists are often accused of disregarding the emotional needs of their patients, but a therapy that proves to benefit both the motorium and mood of PD patients is regarded with suspicion. Even the best non-motor effects achieved by DBS-STN are hardly grounds for envy (not to mention the unknown motor effects of DBS in a healthy person); it is unlikely that neuro-enhancing pharmaceuticals will be rendered obsolete by expensive elective neurosurgery in the foreseeable future. It has, in any case, nothing to do with the permissibility of DBS in PD. Meaningful functional enhancements that would justify neurosurgery for a healthy consumer remain nothing more than hypothetical, and have nothing to do with use of DBS in movement disorders, or, indeed in certain psychiatric disorders; is the difference between DBS for schizophrenia – once again, under the strict proviso that an appropriate site for DBS can be rationally identified – and the use of a powerful neuroleptic more than an emotional fear of stepping upon a slippery slope that leads to cyborgs and Daleks?

The patient is the final arbiter of how well "they feel in their skin": "*legally competent patients are not obliged to live up to or agree with the ideas of authenticity or rationality held by their doctors*" (Pacholczyk 2011). Ethicist Karsten Witt (2013) argues that decisions by a patient regarding DBS must also consider the hypothetical, changed person they will be after surgery, but effectively (and realistically) depicted this "role-playing" as essentially involving no more than the question "Do I want to become that person?" (cf. also Synofzik and Schlaepfer 2008; Glannon 2009).

Philosophical discussions of an altered "self" or "identity" are, in the end, largely intellectual exercises with respect to DBS therapy of movement disorders. The crude localization of personality traits in particular brain regions is no longer current in neuropsychiatric thought, let alone the localization of identity, nor is it envisaged that the addition or subtraction of nerve cells or stimulation of specific nerve regions, as practiced in the therapy of movement disorders, is any more likely to alter identity to any greater degree than pharmacological therapy of these disorders. It is difficult to envisage that even a healthy person could maintain a stable identity if it were to be subject to modification by every structural or functional change experienced by that person in the course of their life. His compatriots may have remarked that Phineas Gage was "no longer Gage" after his horrendous accident, but Gage himself was in no doubt that he, in fact, was.

DBS is, in short, a "softer" neurosurgical approach to movement disorders, allowing an effective intervention that can be suspended should this prove necessary. There are still unresolved issues: the psychological effects of DBS, for instance, may not be as easily reversible as turning off the stimulator, and even some of the immediate neural effects may be of greater permanence than is generally supposed (via neural plasticity, altered firing patterns); these enduring changes may be beneficial (as predicted by the desynchronization hypothesis of DBS: Wilson et al. 2011) or deleterious. Finally, with increased confidence instilled by experience, it may be considered ethical to trial DBS in younger patients, in whom less advanced disease may allow greater potential for slowing the course of disease (see recent positive reports by Kahn et al. 2012; Schuepbach et al. 2013).

Deep Brain Stimulation as an Experimental Procedure

Although now a well-established therapeutic approach in the treatment of PD, DBS has not entirely shed its experimental aspects; indeed, the success of the method has rendered it ideal for experimental purposes:

> Other reasons why DBS, especially STN DBS, virtually eliminated ablative surgery are that DBS can be safely performed bilaterally and that DBS as a technique allows safe and ethically acceptable studies of the brain in living humans. Anatomy, physiology, psychology, cognition, and many other features could be studied by recording and stimulating at various electrical parameters, as well as by structural imaging, functional imaging, MEG, and so forth, using the DBS electrode as a tool that can be externalized, adjusted, manipulated, or turned on or off if needed in single- or double-blind fashion.
>
> Hence, the marriage between DBS and the STN has opened virtually limitless avenues for research, observation, and documentation, resulting in STN DBS becoming by far the most published functional neurosurgical procedure. (Hariz 2012)

This certainly blurs the divide between therapy and research, and between basic and applied research, but every medical intervention is, in effect, an experiment, as the physician can never be certain how a particular individual will respond to a medication or surgical intervention, no matter how well established; the value of both casuistic reports and post-licensing follow-up studies of medications reflects the fact that unexpected effects – ranging from unpredicted benefits to fatal outcomes – may occur in only a comparatively small number of patients, or long term effects might be recognized only when a larger patient collective has been reviewed. The permissibility of an intervention in an individual case is thus not determined solely by whether it is experimental or not, but by the degree of evidence supporting the rationale underlying the intervention, and the informed consent of the recipient. The results of animal studies cannot be transposed directly onto the human patient, with thalidomide providing a spectacular example where safety in animal models inspired false confidence with regard to use of the drugs in humans. Finally, there is a widespread misconception that "scientific medicine" provides patients with guaranteed solutions. Medical science, however, is constantly evolving, and the clinical answer

offered today can never be more than the best currently available; trial and error is inherent not only in experimental medicine and basic science, but also in the ongoing analysis of the outcome of existing therapeutic strategies. Finally, it would be remiss of a physician or surgeon not to maximize the profit for both patient and medical knowledge to be realized in the course of a therapeutic intervention but always according to the maxims that the patient not be harmed or their time wasted, and that the supplementary investigations be conceptually justified and not simply a whim or the emission of a pet hypothesis.

The cited Hariz comment might raise specters of the psychosurgery of the 1950s, or of the neurophysiological investigations of the American psychiatrist Robert Heath, as reviewed by Baumeister (2000) and Stahnisch (2008). Both the institutional and legal frameworks in which such investigations are now conducted, however, ensure that the a return to past transgressions against human dignity is highly unlikely. As noted by Schmitz-Luhn et al. (2012), for example, German law requires that "*just as is the case for any therapeutic treatment*, *the clinical trial must be clinically and factually justifiable*, *the patient must have given his or her informed consent to the trial*, *and the medical entity must adhere to the established rules of professional conduct*." The once virtually unfettered freedom of judgment accorded to lone investigators has not been constrained by ethical considerations, but also by law.

This advance with regard to medical ethics is mostly clearly exemplified by considering a passage from a report on an NIH-supported scientific conference on the experimental use of "depth electrodes" (mostly employed to explore cortical function) in the mid-1950s, published in the NIH annual report:

> It looks as though, with the methods devised up to the present time, that such methods are going to become relatively popular whether this is warranted therapeutically at present or not. It looks as if it is important to encourage publication and discussion and not to allow ethical judgments to drive people "underground", i.e. to prevent publications and full exchange between investigators. This field seems to be acquiring a respectability and a set of ethics which are acceptable to most of the medical profession and to most scientific investigators in the field. (Lilly 1957)

Several features underscore the fact that investigators were operating in a drastically different legal and ethical context to that which now exists in Western countries. A research direction at this point could "*acquir*[*e*] *respectability and a set of ethics*" in the same way a gentleman's club established its rules – by internal discussion of what was most convenient and tolerable for members, rather than being grounded in *a priori* accepted basic human rights. Ethics was a matter of custom among the investigators alone, rather than a consensus view reached by discussion of specific issues by a broader range of interested persons. This partly explains not only the unbridled experimentation of Heath, but of other practices that continue to inspire horror, such as frontal lobotomy and the excessive employment of shock therapies, practiced in the main, it should be noted, not by neurologists or neurosurgeons, but by overconfident psychiatrists. The historical trajectory between practices in this period and current practices is twofold: the direct path connects the

evidence-based neurosurgery for PD of the period with more recent DBS approaches; the second comprises the warning provided by the failure of self-regulation on an individual basis to secure the interests of patients in biomedical research when the ambition of researchers blinded them to the fact that human dignity should not be sacrificed to the scientific enterprise, no matter how noble its aspirations.

On the other hand, it would unreasonable to proscribe the pursuit of a promising intervention purely on the basis that its mechanisms were not fully understood; this would, for example, also disallow the use of most surgical anesthetics, as well as the "off-label" use of licensed pharmaceuticals for otherwise untreatable conditions. Caution must naturally be applied where the mode of action of an intervention has not been completely elucidated; but scientific medicine has always been a pragmatic endeavor, whereby effective therapies were developed and adopted on the basis of their apparent efficacy, without always knowing why they were effective. Intervention in the brain demands particularly caution, both because of its complexity and the very incomplete understanding of the basis of this complexity, but advances in the areas under discussion will only be achieved by carefully controlled trial and error. Future observers will perhaps regard early twenty-first century DBS techniques as frighteningly primitive, but more satisfactory procedures will develop only through evolution from these beginnings.

A similar situation is evident in the history of DRT for PD. There was a rational basis (the basal ganglia dopamine deficit) for introducing L-DOPA therapy in 1961, but knowledge of the biochemistry of PD was rudimentary: How, for example, could the striatal dopamine deficit be causally related to the hallmark of parkinsonism, nigral degeneration, given that a nigro-striatal pathway had not yet been described in humans? How did dopamine actually work in the CNS? – that it was a neurotransmitter was not yet universally accepted, and many doyens of catecholamine research rejected a role for catecholamines in behavior altogether. The issue was further complicated shortly afterwards by the dopamine hypothesis of schizophrenia: could "too much" dopamine supplementation cause psychosis? The final breakthrough for the therapy was achieved despite the marked negative side effects of high dosage L-DOPA, and its success remained unbroken by the rapidly growing awareness of dyskinesias and other side effects associated with chronic therapy. It was only after L-DOPA had been established as the "gold standard" of PD therapy that the different dopaminergic neural systems were mapped, basal ganglia circuits defined, and families of dopamine receptors identified, contributing to comprehension of the mechanisms underlying the desired and undesired effects of L-DOPA: whereby experience gained in the therapy of PD interacted with laboratory findings to promote advances in both the fundamental research and clinical spheres. Genuinely evidence-based medicine involves a continuous feedback between theory and practice that permits the refinement of neuroscientific models that underlie both theory and therapy.

Neither DRT nor DBS are perfect in their current configurations, but the benefit afforded patients who would otherwise be condemned to the misery unfamiliar to

most Western neurologists of the L-DOPA era means that each can be employed and further developed with clear conscience.

Overview of General Neuroethics of Deep Brain Stimulation for Parkinson's Disease

Autonomy

The impact of current therapeutic strategies for PD does not threaten the stability or continuity of the patient's identity or autonomy. Changes in decision-making are attributable to the increased spontaneity and freedom of expression achieved by therapy, and as such may have undesirable consequences, but do not reflect an insidious "change of character."

The nature of DBS means that treatment is provided by a limited number of centers, presumably including particularly confident advocates of the normal procedures. There are currently only two major manufacturers of the DBS devices employed in PD, so that the clinical trial material assembled on their websites, together with the clinical leaders of those trials, will exert a greater influence on the opinions of prospective patients (who may not recognize the promotional element of "information pages") and their physicians than is achieved even by insistent pharmaceutical advertising. This influence is amplified when the popular press uncritically adopts the manufacturers' claims regarding treatment breakthroughs (Laryionava et al. 2010b; Fins et al. 2011; Gilbert and Ovadia 2011; Schermer 2011).

Non-Maleficence

The selection of therapy for an individual patient must consider the nature of the therapy, the potential side effects, and the current state of the patient; caution must be especially exercised with respect to the physical, cognitive, and emotional status of the patient before undertaking surgery, including their attitudes to surgery and calculated risk. Minimization of the stresses imposed by post-surgery adaptation by comprehensive discussions of what the surgery can and cannot achieve, as well as the consequences this will have for the patient and their families and other close contacts is essential. Patients with a history of depression, psychiatric disease, or impulse control disorders should be carefully monitored both before and subsequent to surgery.

Beneficence

This aspect is assured by implementing only those therapeutic strategies in the treatment of a patient that both have firm theoretical and experimental bases. Clear consensus decision strategies with respect to treatment options

have been established in both the United States and Europe; a conservative approach, commencing with L-DOPA and proceeding to more invasive techniques (including DBS) only where absolutely necessary, minimizes the risk to patients. DBS recipients also require long term specialist care that exceeds the needs of a cardiac pacemaker recipient, for example; the changes associated with successful treatment, in particular, require support from a variety of medical and social support specialists (Fins 2009; Bell et al. 2011b).

Justice

The major issue is whether the benefit afforded by therapy justifies the costs involved. Estimates of the costs associated with DBS indicate that, while the initial surgery is expensive (tens of thousands of dollars), the long-term costs are lower than those of L-DOPA therapy alone, with one study indicating that the initial costs can be recouped in as little as 2.2 years. In particular, expenditure for DRT is markedly reduced, a welcome parallel to the benefit for the patient of their reduced reliance on these medications (reviewed: Valldeoriola et al. 2007; Bell et al. 2011a; Dams et al. 2011; McIntosh 2011; Toft and Dietrichs 2013).

Concluding Remarks

Although ethical questions certainly arose with each new therapeutic approach for PD since the introduction of L-DOPA in the 1960s, and any strategy that alters dopaminergic transmission or basal ganglia function may have an impact upon mood and mentation, discussion of such issues achieved significant volume only with the establishment of DBS-STN – and even then, as several authors have noted, only since 2010, more than 20 years after the introduction of DBS for PD. By this time, a not inconsiderable professional literature concerning the mental and emotional effects of DBS in PD was already available. There was no lack of awareness of the importance of the problems involved, but they were addressed in the practical manner of those concerned with people seeking help: They sought to elucidate factors that might assist in identifying patients at risk of negative outcomes; the importance of multidisciplinary support both before and after surgery was recognized.

There are two interlocked reasons for the uneasiness sometimes expressed with regard to DBS in PD: Firstly, the implantation of a man-made device in the brain is perceived to be intrinsically more disturbing than the use of pharmacological agents to achieve the same ends (and with more frequent adverse effects), or even stimulation of or neurotransplantation in the spinal cord; and secondly, it is seen as the first step to the development of implants with the specific aim of controlling behavior. Such fears are fuelled by press reports of apparent advances in

"mind-reading" by brain imaging equipment, or of systems that will allow quadriplegics to control a computer "directly with their thoughts." Indeed, attention turned to the ethics of DBS for PD only when extrapolation of the use of DBS to the therapy of psychiatric disorders was mooted, triggering memories of older style psychosurgery. A recent survey of German medical students, for instance, found almost unanimous approval for the use of "brain pacemakers" for the management of PD, much less support for their application to the treatment of alcoholism or depression, and almost total rejection for their use for neuroenhancement (Laryionava et al. 2010a).

While the disquiet surrounding implanted devices is quite understandable and cannot be ignored, nor should the fact be overlooked that this conflation of issues and impressions is largely irrelevant to discussion of the ethics of DBS when applied to movement disorders. DBS-STN may improve mood and mental vigor in of PD patients, but thoughts, memories, and goals – the core features of identity – are untouched. It is, in any case, unexpected that improved mood is viewed with suspicion, rather than as a welcome bonus; as Müller (2010) has argued, DBS for PD should not focus purely on motor symptoms, but also on cognitive, emotional, and social factors.

The central problem for skeptics was captured by Merkel et al. (2007) in their declaration:

> Practically no intervention in the structure or functioning of the human brain can be undertaken in complete certainty that it will not affect mental processes, some of which may come to play a key role in a person's self-concept

It is a declaration, however, that applies to any CNS intervention, from taking aspirin for a headache to a complete cerebral lobe extirpation, and as such offers little guidance for the ethical approach to the therapy of PD. Further, it is already possible to define critical brain regions where one should proceed with extreme caution, and research will broaden understanding of which other areas need to be handled with care. This will proceed, as neuroscience always has, by trial and error, braked but also legitimized by ethical boundaries to what research in the CNS is permissible.

I would plead for a less intensively philosophical approach to identity in considering the permissibility of direct CNS interventions in PD, particularly as gaps in our knowledge regarding the relationship of brain and mind are greater than those regarding the extrapyramidal system. It is clear that mind and movement are no more interwoven than they are in the basal ganglia, and this means that any attempt to address movement disorders must also address the attendant psychiatric aspects that, after fifty years of DRT, are increasingly familiar. But pragmatic ethics are required in the clinic, and they should be focused upon the physical and mental well-being of the patient as judged by the patient themselves. Humanistic medicine cannot be a slave to technology, but nor also to quasi-metaphysical speculation that distracts from assisting patients regain autonomy. In a very real sense, the physician hopes that their patient emerges a new person through their therapy – a freer, happier person, more able to pursue their interests than they once were.

Risk and Consent in Neuropsychiatric Deep Brain Stimulation: An Exemplary Analysis of Treatment-Resistant Depression, Obsessive-Compulsive Disorder, and Dementia

Abstract

Interest in deep brain stimulation (DBS) for treatment-refractory psychiatric disorders has raised ethical concerns about the adequacy of safeguards for human subjects. The nature of DBS and potential vulnerability of participants have raised worries about whether study participants have capacity to give informed consent (including understanding the risks associated with DBS and the likelihood of personal benefit), and can appropriately distinguish between DBS research and clinical care. Empirical inquiry into these concerns suggests that the vast majority of prospective participants under consideration for early trials of DBS for treatment-resistant depression (TRD) had adequate decisional capacity. While these patients considered DBS for various and often unique

reasons, most understood the risks and had reasonable expectations of benefit. These results suggest that given appropriate procedures, patients with TRD can provide informed consent to DBS research. Further attention is needed to understand patients' considerations for DBS research, and to evaluate procedures to enhance appreciation of distinctions between research and clinical contexts. Similar inquiry on DBS research for other psychiatric disorders is needed, particularly because greater cognitive impairment is associated with worse performance on measures of decisional capacity. Safeguards such as surrogate consent should be considered (and their use reported) when studies enroll patients with cognitive disorders, such as Alzheimer's disease and other dementias. Research is needed into whether patients with obsessive-compulsive disorder are more likely than those with depression to lack adequate capacity.

Introduction

Following the successful use of deep brain stimulation (DBS) in ameliorating symptoms associated with severe, refractory Parkinson's disease, essential tremor, and primary dystonia (Lyons 2011; Weaver et al. 2012), and its more recent use in treating less severe forms Parkinson's disease (Schuepbach et al. 2013), there has been burgeoning interest in applying DBS in the treatment of a number of psychiatric illnesses. A growing series of small studies suggest that DBS can be an effective intervention for treatment-resistant depression (TRD), obsessive-compulsive disorder (OCD), and Tourette's syndrome (Bewernick et al. 2010; Flaherty et al. 2005; Goodman et al. 2010; Greenberg et al. 2006; Holtzheimer et al. 2012; Holtzheimer and Mayberg 2011; Kennedy et al. 2011; Lozano et al. 2008, 2012; Malone et al. 2009; Mayberg et al. 2005). More recent research has focused on using DBS for Alzheimer disease, other dementias (Laxton and Lozano 2012), anorexia nervosa (Lipsman et al. 2013), and for substance addiction although, thus far, outcomes data are limited.

From its earliest use, DBS has sparked ethical debate (Siegfried et al. 1980). In anticipation of the research application of DBS to treat psychiatric illness, however, increasing attention and concern has been directed toward a specific set of empirical and normative issues. These include the need to provide adequate protections for human research subjects through robust informed consent with clear articulation of the risks, potential benefits, and alternatives to DBS. There is concern that prospective participants, by virtue of their mental illness, may lack decision-making capacity regarding enrollment or may have misconceptions either about the likely benefit from DBS or the experimental nature of the study. Additional concerns include the precipitous application of DBS for treatment-refractory illnesses in the absence of appropriate justification, and ensuring rational scientific methodology and transparency of researchers' conflicts of interest (Bell et al. 2009; Dunn et al. 2011; Fins et al. 2011b; Rabins et al. 2009). Others have cautioned against selective reporting of DBS research in the scientific literature (Schlaepfer

and Fins 2010) as this may contribute to the misrepresentation of DBS efficacy in the lay media (Racine et al. 2007) and, perhaps more importantly, may prematurely or inaccurately guide both clinical practice and future DBS research.

There has been long-standing concern about whether individuals with serious psychiatric illness are able to make rational, informed decisions regarding research enrollment (Elliott 1997; Michels 2004; National Bioethics Advisory 1998; National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research 1978). Yet, numerous empirical assessments of subjects with a range of mental illnesses suggest that a majority have the requisite decision-making capacity (Appelbaum et al. 1999; Cohen et al. 2004; Lapid et al. 2003). Thus, although intended to safeguard human subjects, concerns about the decisional capacity of persons with mental illness may ironically constitute a form of "benevolent stigmatization" (Synofzik and Clausen 2011) and thereby unnecessarily obstruct research that may lead to effective treatments. Given the limited knowledge about the risks and potential benefits of DBS and the invasive, high-risk nature of DBS research, Dunn and colleagues (Dunn et al. 2011) called for empirical examination of various aspects of the informed consent process to run parallel with the emergence and evolution of DBS clinical trials, and outlined key additional safeguards for protecting participants. Below, we discuss results of this empirical ethics work (Christopher et al. 2012; Fisher et al. 2012; Leykin et al. 2011), highlight some of the outstanding questions and areas for future inquiry, and describe how empirical ethics may similarly guide DBS research for other psychiatric disorders.

DBS for Treatment-Resistant Depression

Early DBS research for psychiatric disorders was focused on TRD because of its high prevalence and devastating effects on patients (Rush et al. 2006; Trivedi et al. 2006). Pilot data suggested that 40–60 % of patients with TRD experienced 50 % or greater reduction in symptom severity when treated with DBS (Bewernick et al. 2010; Lozano et al. 2008; Malone et al. 2009). In addition to its potential for benefit, DBS held other advantages over ablative neurosurgical procedures (also considered for treating refractory psychiatric disease), including stimulation reversibility, adjustability, and revisability. However, although promising, these studies offered limited data on the short-term and no data on the long-term antidepressant efficacy of DBS for TRD.

At the time these pilot data were reported, the known risks associated with DBS were largely extrapolated from research and clinical experience in treating movement disorders. The implantation itself required stereotactic brain surgery in order to place electrodes into the brain and also subcutaneous implantation of a pulse generator/battery pack along the chest wall to power the DBS electrodes. Known risks associated with DBS implantation included intracranial hemorrhage, seizure, infection, hemiparesis, and a small risk of death (Deuschl et al. 2006a, b; Herzog et al. 2003; Synofzik and Schlaepfer 2011). Risks specific to the stimulation site

included increased suicide rate in Parkinson's patients as seen with subthalamic nucleus DBS (Voon et al. 2008), mania in TRD and OCD patients who received anterior internal capsule DBS (Greenberg et al. 2008; Malone et al. 2009), and a number of other mood, cognitive, and functional concerns (Synofzik and Schlaepfer 2011).

There was an expectation that other risks would be identified when larger studies were conducted. Thus, both the known and unknown risks were deemed to be important considerations for any subject with TRD considering enrollment in a DBS trial. Additional factors had to do with maintenance issues associated with DBS implantation, including surgical replacement of implanted battery packs, repair and replacement of dysfunctional DBS components, need for long-term follow-up and monitoring, and inconvenience issues from having to avoid metal detectors, strong magnetic fields (e.g., MRI scanners), and excessive heat (e.g., therapies such as diathermy) (Farris et al. 2008).

The first two multi-site, industry-sponsored clinical trials (Advanced Neuromodulation Systems 2009; MedtronicNeuro 2009) targeted the subcallosal cingulate gyrus (Cg25). The investigators of these trials had to ensure that potential subjects undergo a thorough consent process that included discussion of the known and unknown risks and potential benefits of DBS for TRD, while avoiding exaggeration of potential benefits.

Prospective participants in these two trials were also invited to participate in an add-on study that evaluated the following aspects of their decision-making regarding entering the DBS trial: (1) their capacity to provide informed consent (based on objective measurement of their trial-related understanding, appreciation, reasoning, and expression of a choice); (2) their perceptions of risks and inconveniences, expectations of benefit, and motivations regarding enrollment; and (3) their ability to accurately distinguish the intent and procedures of the trial from ordinary clinical treatment.

Capacity to Consent: Empirical Data

Capacity to provide informed consent to the DBS trial was assessed with the MacArthur Competence Assessment Tool for Clinical Research (MacCAT-CR) (Appelbaum and Grisso 2001). The MacCAT-CR requires a semi-structured, open-ended interview that is designed to be adapted to the specific content of any research protocol. Thus, a unique version of the MacCAT-CR was developed for each of the two clinical trials.

The MacCAT-CR is divided into subscales (with higher scores indicating better performance) to rate an individual's ability in four key competence domains: Understanding (i.e., ability to comprehend and recall the disclosed details of the study including its purpose, duration, procedures, risks, and potential benefits), Appreciation (i.e., ability to apply the disclosed information to one's own situation), Reasoning (i.e., ability to critically compare research participation with other treatment options), and Expression of Choice (i.e., clearly indicate and sustain one's own decision regarding enrollment).

Of the individuals who met eligibility criteria for one of the two DBS trials, agreed to participate in the add-on study, and completed the MacCAT-CR assessment, the majority demonstrated sufficient capacity to give informed consent (Fisher et al. 2012). On the Understanding subscale (with a possible range 0–38), all but one subject score 33 or higher and 18 out of 28 subjects scored perfectly. On the Appreciation subscale (with a possible range 0–6), 27 out of 29 subjects scored perfectly, with one subject missing one item and another missing two items. On the Reasoning subscale (with a possible range 0–8), 21 out of 25 subjects scored perfectly, with two subjects missing one item and two other subjects missing two items. All subjects scored perfectly (range 0–2) on Expression of Choice.

It should be noted that this sample represents a very small, generally well-educated and pre-screened group, and that the discussions leading up to an informed consent decision were extensive, often occurring over multiple sessions and lasting for several hours. Nevertheless, the overall high performance of these individuals on the MacCAT-CR undermines the assumption that individuals with TRD lack the requisite decisional capacity to enroll in DBS research. This finding, which is consistent with findings from a number of other studies of decisional capacity among persons with mental illness (Appelbaum et al. 1999; Candilis et al. 2008; Cohen et al. 2004; Grisso and Appelbaum 1995; Jeste et al. 2006; Lapid et al. 2003), suggests that serious mental illness alone should not preclude patients from enrolling in DBS research (or consenting to DBS treatment).

Perceptions of Risks, Expectations of Benefit, and Motivations

Prospective participants in these DBS trials were also asked a series of questions to evaluate their perceptions and ratings of the study's risks (DBS surgery, depression questionnaires, MRI, neuropsychological testing), the potential for personal benefit, the potential for the study to benefit others in the future (by advancing knowledge about treating depression), and their motivation to participate in order to help others (i.e., altruism).

Of the 30 participants that answered these items, nearly all rated the risks associated with completion of depression questionnaires and neuropsychological testing as minimally risky. All participants rated the DBS surgery (implantation) itself as the riskiest part of the study (21 rated it as a "moderate risk" and four as a "minor increase over minimal risk"); no participant rated the surgery as "minimal risk." All but one participant rated the surgery higher than all other study procedures. When comparing how participants rated the risk of each procedure to oneself with people generally, the mean risk ratings did not differ significantly, with the average risk rating being in the "moderate" range (Leykin et al. 2011).

When asked to rate the likelihood of benefiting from the DBS study (from 0 to 5, with a higher score indicating greater likelihood of benefit), on average, participants rated others as being more likely to benefit than themselves (mean of 4.0 (SD = 0.8) vs. 3.21 (SD = 0.6), paired t (27) = −4.53, $p < 0.001$). Participants' ratings of personal risk from the study did correlate with their ratings of study risks to people

in general ($\rho = 0.45$, $p = 0.01$) but did not relate to their ratings of personal benefit ($\rho = 0.09$, $p = 0.63$) (Leykin et al. 2011).

Distinguishing Between Research and Clinical Care

Participants were also asked 8 true/false items intended to assess their ability to accurately distinguish between key ways in which the DBS trial (or research in general) differed from ordinary clinical treatment (i.e., determine whether they had a therapeutic misconception). These included questions about the study's purpose, the likelihood of personally benefiting from the study, and whether the study protocol permitted individualization of treatment for each participant. Although 11 of the 31 participants (35.5 %) gave the correct response for all eight items, the remainder (64.5 %) answered at least one incorrectly. Seven participants (22.6 %) missed two items, and one (3.2 %) missed three items. The items that were most commonly answered incorrectly (by seven participants or 22.5 %) were: "The study is mostly intended to help me" (which is false), and "The research physician cannot add any other medication for depression during the first seven months of the study, even if he or she thinks it would help me" (which is true). Six participants (19 %) also incorrectly indicated that the following item was true: "My own treatment for depression will certainly be improved as a result of this study" (Leykin et al. 2011). Of note, there was no correlation between depression severity and the likelihood of having therapeutic misconception (Fisher et al. 2012).

The prevalence of therapeutic misconception in this group comports with that found among other psychiatric and non-psychiatric research subjects (Appelbaum et al. 2004; Daugherty et al. 1995, 2000; Dunn et al. 2006b; Henderson et al. 2006). It is noteworthy that although these participants do not appear to have unrealistic expectations of personally benefiting from DBS, many nevertheless view the trial as being primarily intended to help them, believe the researchers are able to individualize their treatment, or believe their own depression treatment will certainly improve by being in the study.

Participant's responses to the MacCAT-CR interview were also qualitatively analyzed to examine the influences that guide their decisions regarding enrollment in the DBS trial (Christopher et al. 2012). Not surprisingly, participants cited a wide range of disease- and treatment-related factors. Most commonly were having exhausted existing treatment options (65.4 % of participants), specific ways in which they hoped DBS would improve their lives (84.6 %), inconveniences associated with the study protocol (76.9 %), and specific risks associated with the DBS surgery (53.8 %). Less frequently reported influences included wanting to take initiative in trying to treat their depression (26.9 %), believing that DBS might be more effective because it represented a new and different kind of treatment (30.7 %), hoping their participation would help others or advance science (i.e., altruism) (26.9 %), and the possibility that DBS might be effective (19.2) or not effective (34.6 %). This group's high prevalence of being motivated by a perceived lack of other treatment options and the novelty of the protocol

intervention (i.e., DBS) is consistent with findings on the motives of participants in other early-phase clinical trials (Nurgat et al. 2005; Shannon-Dorcy and Drevdahl 2011). Yet, despite a high number of shared factors, no single consideration seemed to be the only factor in determining one's enrollment decision; indeed, each participant tended to have their own unique set of motives.

DBS for Obsessive-Compulsive Disorder

DBS for obsessive-compulsive disorder (OCD) is also in relatively early development as a treatment for patients who remain symptomatic after multiple treatment trials. OCD is a devastating disorder for these patients, significantly reducing quality of life, curtailing productive and enjoyable daily functioning, and severely constraining the patient's world (Markarian et al. 2010). A significant portion of patients with OCD also suffer from comorbid psychiatric syndromes, most commonly major depression, other anxiety disorders, alcohol use disorders, tics, eating disorders, and other compulsive behaviors (Torres et al. 2006). In addition to the symptoms borne by patients, families suffer alongside patients, with daily work and social functioning constrained by symptoms that can essentially imprison the patient (Cicek et al. 2013).

DBS for OCD presents a set of ethical concerns that overlaps those associated with DBS for depression. There are some differences, however. An important difference is that DBS for OCD has received a humanitarian-device exemption (HDE) from the United States Food and Drug Administration (FDA), meaning that DBS can be used outside of clinical trials for individuals with treatment-refractory OCD. This approval has been criticized by some (Fins et al. 2011a) as premature, given the limited efficacy data available at the time of the approval. Thus, from the perspective of many in the field, despite the HDE approval, DBS remains experimental for OCD. From an ethics perspective, ensuring that patients understand the relatively limited data remains important to ensure that consent is fully informed.

There are no existing empirical studies that have examined decision-making capacity for DBS research in individuals with OCD. In fact, to our knowledge, there are no studies specifically examining decision-making capacity of patients with OCD for any type of clinical research. Nevertheless, concerns about the informed consent process, the desperation of patients with treatment-refractory illness, and the abilities of patients to understand, appreciate, and reason adequately regarding DBS trials parallel those about patients with severe and refractory mood disorders.

Lipsman et al. (2012) enumerated these concerns as follows. First, they noted that patients with treatment-resistant psychiatric conditions, such as depression or OCD, may be vulnerable to "desperation." Unfortunately, however, no operational definition of "desperation" – and no method of measuring this construct – exists in the context of clinical trials. Furthermore, patients with treatment-resistant OCD may be more liable to expect that this novel procedure will benefit them personally, not fully grasping that the intervention is still essentially experimental – even in the presence of an HDE. Lipsman and colleagues express this concern as follows:

> Research, however, into psychiatric DBS, including OCD, is still very much an area under active investigation and as such, a patient's referral to a neurosurgeon typically constitutes the crossing of an invisible border, from treatment to research. This division is rarely explicitly addressed and enhances the vulnerability of these patients by potentially disturbing the consent process, in several ways. (Lipsman et al. 2012, p. 108)

The authors elaborate that patients may view the intervention as an effective treatment when it is essentially still investigational. They also raise the issue of whether referral to a neurosurgeon "without explicit discussion of the therapeutic misconception" (Lipsman et al. 2012) may take advantage of the patient's sense of desperation and in essence confirm to the patient that their condition is desperate. However, no evidence is available to gauge whether these concerns are supported. Until such questions are examined using appropriate, systematic, and thorough methods – particularly in-depth interviews with patients with these disorders (including those considering DBS as well as those not considering DBS), it is nearly impossible to generalize about "desperation," its effects on decision making regarding DBS, or how to address these effects.

Similarly, no research is available regarding levels, predictors, or correlates of decision-making abilities (together comprising capacity to consent) of patients with OCD in the context of research participation decision making. Studies of patients with various psychiatric disorders suggest that the most robust correlates of decision-making abilities, as measured by, e.g., the MacCAT-CR, are cognitive measures, particularly working memory, processing speed, and language abilities (Dunn et al. 2006a, 2007; Palmer et al. 2004; Palmer and Savla 2007; Stroup et al. 2005). Given impairments in emotional processing and cognitive flexibility in patients with OCD, and the detailed nature of the procedures and risks related to DBS, it would be informative for investigators to gather data regarding the decision-making abilities, motivations, risk and benefit perceptions, and potential therapeutic misconception in patients with OCD considering DBS. It would also, in our view, be particularly valuable to examine the actual content and processes of the discussions between the DBS team and the patient, in order to determine whether there are discrepancies between the perspectives and expectations of clinicians and investigators and those of patients.

DBS for Alzheimer's Disease and Other Dementias

The enormous personal, familial, societal, and financial toll of Alzheimer's disease (AD), currently the sixth leading cause of death in the United States (Thies and Bleiler 2011), will only continue to grow, given the projected growth in AD as the population ages (Hebert et al. 2013). Thus far, pharmacologic interventions have been disappointing, with modest effects on the trajectory of the illness. Calls for enhanced research efforts have grown more urgent (The Alzheimer's Study Group 2009). Into this intense environment, a small number of investigators and centers have begun early-phase trials examining the potential for DBS to slow the progression of AD, based, at least initially, on a serendipitous finding of enhanced memory in a single patient implanted for another indication (Hamani et al. 2008).

Ethical issues surrounding DBS for AD (or other disorders characterized by progressive cognitive deterioration, but here we will focus on AD as that is where the trials are now focused) again mirror those for depression and OCD, but with some additional, important issues related to the cognitive impairment that is the hallmark of AD. Specifically, decision-making capacity for research in people with AD is much more likely to be impaired, depending on the stage of disease, and, unlike other psychiatric illnesses, will certainly deteriorate as the illness progresses. Furthermore, consent for research will then need to be a family affair, with surrogate decision makers providing consent with concurrent patient “assent.” These factors raise unique ethical concerns.

First, there is the unresolved question of whether “desperation” experienced by patients and families dealing with this devastating illness may unduly influence people to accept a research intervention that they otherwise would not. Anecdotally, reports in the media suggest that desperation plays a role in research decision making, but again, there are no systematic data to help put such reports into context. There are also no data directly comparing the motivations of patients and families enrolling in DBS research versus other types of AD intervention research, such as pharmacologic or non-pharmacologic trials. There are also no comparative data regarding “desperation” in the context of DBS for dementia versus “desperation” in the context of research for other serious illnesses (e.g., cancer, Parkinson’s, epilepsy, multiple sclerosis, etc.). Such comparisons would be informative, as there may or may not be evidence that the patients and families enrolling in DBS research weigh risks and benefits differently than those enrolling in other types of research. Again, assumptions unsupported by evidence do no favors to the research community nor to the patients and families they ultimately serve. Finally, it remains vital that investigators and others (e.g., those in the media) do not hype the “promise” of this intervention when seeking participants or discussing early results (Racine et al. 2007; Schlaepfer et al. 2010), given the potential propensity of these patients (and other patients with serious disorders) to believe that early “positive” findings indicate efficacy, when in fact much more data are needed.

Second, there is clear evidence from the decision-making capacity literature that people with AD eventually lose the requisite abilities to provide consent to research (Kim 2006; Kim and Caine 2002). The transition from mild to moderate AD appears to be the vulnerable period for loss of decisional capacity for research decision making. Therefore, assessment of decision-making capacity needs to be incorporated into any research protocol that involves people with AD in DBS (or other non-minimal risk) research. Indeed, decisional capacity must be frequently reassessed, since a patient with AD who has decisional capacity to give consent at enrollment may lose that capacity at any subsequent point in the research study. Although periodic re-evaluation of capacity is a generally accepted requirement in any longitudinal study (e.g., “re-consenting” at follow assessments), it is particularly important in the context of DBS for AD, given the potential for adverse effects from DBS that could not reasonably be anticipated at the time initial consent was given. Ideally, then, an initial informed consent procedure should include a discussion of the possibility that the participant will lose decisional capacity

after enrollment. A prospective participant may choose to specify circumstances under which they would want their consent to be revoked or identify a surrogate who would assume responsibility for giving ongoing consent. In one of the initial studies, it is unclear that any capacity assessment was conducted (Laxton et al. 2010), although it was stated that the local ethics review board monitored the informed consent process and "obtained consent independent of the investigators" (Laxton et al. 2010). This is an important point, given that the range of Mini-Mental State Examination scores at the preoperative assessment timepoint was 15–27 (a wide range of cognitive impairment), suggesting that the use of an independent consent procedure was an appropriate safeguard. However, it would also be helpful to know more about the consent procedure, whether any educational intervention strategies were used given the level of cognitive impairment, and whether any standardized, validated capacity assessment method or tool was employed, and whether decisional capacity was reassessed at any point (assuming it was evaluated at the outset). Given the higher risk nature of the intervention, as well as the limited knowledge base about the potential benefits of the intervention for people with AD, the threshold for "adequate" capacity arguably ought to be more stringent than for lower risk protocols. Thus, there remains a need for further attention to the adequacy of the capacity screening and consent procedures for these early-phase studies of DBS for AD.

Third, when patients do lack adequate capacity to provide research consent, investigators must rely on a surrogate decision-maker (most often a family member, such as a spouse or adult child) to provide consent to the protocol (Dunn et al. 2012). In the Laxton study, the investigators do not clearly state how many of the six participants provided their own consent versus how many had surrogates' consent for them (with, presumably, assent provided by the patient). There are numerous ethical dimensions of surrogate consent that need to be considered in any research protocol, but that deserve particular attention in the context of highly invasive and novel interventions. First, ethical guidelines (and some state laws) related to surrogate decision making (Saks et al. 2008) recommend a specific hierarchy of standards for how surrogates should decide on behalf of the patient or subject. First, if there is an advance directive or other evidence of known wishes, the surrogate is supposed to act in accordance with that advance directive. In the absence of an advance directive (as is most frequently the case in research), surrogates are supposed to employ "substituted judgment" – their understanding of what the patient would have wanted if capable. When this is not possible, the surrogate is ideally to decide based on the patient's best interests. A number of studies, however, have shown that, particularly in the context of research participation, surrogates may have difficulty actually using "substituted judgment," given that many people have not expressed premorbid wishes regarding this specific situation (Hare et al. 1992; Hirschman et al. 2006; Seckler et al. 1991; Shalowitz et al. 2006). Instead, surrogates tend to use a combination of best interests and substituted judgment, and describe trying to honor the patient's wishes and values, while trying to maintain the patient's quality of life (Black et al. 2010; Overton et al. 2012). Surrogate decision makers' processes do not neatly reflect the

standards and guidelines that presently exist. For investigators and ethics reviewers, this creates a difficult situation, as they are charged with upholding ethical principles (e.g., "respect for persons" and "beneficence") in a group with significant potential vulnerability. Surrogate consent, it should be noted, does not relieve the investigator of other obligations to uphold ethical duties in research, and may add other duties, such as re-assessment of capacity as well as ongoing monitoring of patient assent to continue participating. In addition, it is not known to what extent, if any, surrogates have a therapeutic misconception with regard to research. This is another important area in need of empirical study.

Conclusion

While deep brain stimulation holds considerable promise in providing relief to a number or debilitating and treatment-refractory psychiatric disorders, the clinical research needed to objectively evaluate this potential is both high risk and, at present, in an early phase. The risks, inconveniences, novelty, and complexities of such research, and the fact that these patients, by definition, have a paucity of alternative options to treat their mental illness, underscore the need for a thorough and thoughtful approach to engage them in informed consent discussions to participate in clinical DBS research. The existing empirical work examining the informed consent process and decision making for enrollment in DBS research, which focuses exclusively on DBS for TRD, suggests that, under the current informed consent process, the majority or eligible participants have adequate decision-making capacity and understanding of the risks associated with DBS. Many participants nevertheless seem to have misconceptions about the nature of the clinical trial, confusing aspects of the DBS study with routine clinical treatment. Although not specific to this research population, the high prevalence of this phenomenon is worrisome, given the extensive nature of the informed consent discussions required for DBS trial consideration. On closer inspection, participants also describe idiosyncratic and varied factors that guide their enrollment decisions. Taken together, these findings suggest a more personalized approach to informed consent to DBS trials may be needed, beginning with a discussion that seeks to elicit prospective participants' motives, fears, and hopes for considering a DBS trial, and that carefully probes and corrects for therapeutic misconceptions in addition to ensuring their requisite understanding of the trial's procedures, risks, and potential benefits.

In the context of DBS for OCD or AD, there are no empirical data specifically examining capacity to consent to DBS research; therefore, any conclusions are necessarily speculative. However, concerns about patients' and families' "desperation" for treatment surround DBS for these disorders as well. Moreover, for disorders characterized by cognitive impairment, such as AD, additional safeguards related to capacity assessment and surrogate consent should be considered. Attention to addressing participants' and families' personal concerns, as well as trying to understand motivations for participating, should be the focus of future empirical studies in DBS research ethics.

As potential disease targets for DBS expand – e.g., to addictions or eating disorders, as well as potentially to less severe forms of mood and cognitive disorders – we anticipate that there will be intensified focus on these and other ethical issues that relate to the nature of the intervention and the types of disorders that are the subject of study. As with all research involving human subjects, continual vigilance of those entrusted with the scientific and ethical conduct and oversight of research will be required. Further conceptual and empirical work will also be needed to continue to inform discussion and debate regarding the ethical application of these novel therapeutics.

Devices, Drugs, and Difference: Deep Brain Stimulation and the Advent of Personalized Medicine

Abstract

In this chapter, the specific challenges of device regulation are addressed with the suggestion that this analysis might be optimized by analogy to personalized medicine, now ascendant in molecular therapeutics. The challenge of device versus pharmaceutical regulation is made through the example of deep brain stimulation (DBS). Unlike drugs, devices are few in number, expensive to develop and administer, and require discrete medical-surgical interdisciplinary expertise. They are personalized in their scope, are therapeutic and investigative tools, and uniquely face barriers related to intellectual property exchange and conflicts of interest. The recent controversy over FDA's Humanitarian Device Exemption (HDE) of DBS in the obsessive-compulsive disorder is offered as evidence of regulatory insufficiency and the failure to distinguish research from therapy due to the therapeutic misconception. An alternative fiscally and methodologically viable research pathway is advanced for quality DBS research.

The conclusion is on a hopeful note, with the speculation that the advent of personalized medicine in other investigative realms may provide innovative solutions to regulation which promote scientific discovery and meet patient-centered needs.

A Pharma Provenance

Although device regulation is within the purview of the US Food and Drug Administration, this responsibility is notably not in the agency's title. This is more than a semantic omission. It is reflective of the agency's history and far greater role in the regulation of pharmaceuticals (Carpenter 2010), a fact which has consequences for the oversight of devices which follow a regulatory pathway similar to that of drugs, even though there are fundamental differences between drugs and devices.

One of the salient differences between these two sectors is their relative size. Big pharma dwarfs the device industry in economic impact and the number of companies operating in the space. As of this writing in late November 2012, Medtronic has the largest market capitalization of any pure device manufacturer with a value of $43.61 billion. To put this figure into perspective, there are seven pharmaceutical houses with market caps over $100 billion each (Reuters 2012). This figure includes Johnson & Johnson which makes drugs, devices, and consumer products and had $25.8 billion sales in its medical device and diagnostic segment in 2011. This is coupled with $24.4 and $14.9 billion in sales from its pharmaceutical and consumer markets (Johnson and Johnson 2011).

Notwithstanding Johnson & Johnson and its presence in multiple marketplaces, the difference in financial scope between the drug and device sector is quite significant. For example, the combined value of the *top 22* device manufacturers with market caps over $1 billion is *less* than the value of Pfizer, a pharmaceutical company valued at $179.2 billion, or Johnson & Johnson with its more blended portfolio and a market cap of $192.2 billion (Reuters 2012).

The relative size of the sectors influences oversight with the importance of drug regulation quantitatively dominating the regulation of devices and qualitatively informing models of regulation. As we shall see, one of the challenges confronting those who would regulate medical devices is an over reliance on approaches and methods borrowed or derived from the regulation of the pharmaceutical industry. This pharma provenance is unfortunate because there are salient differences between drugs and devices in their development, deployment, prevalence, and markets. In this chapter, I will explore the specific challenges of device regulation (Fins et al. 2011d) through the prism of deep brain stimulators employed in the treatment and study of neuropsychiatric conditions. I will primarily focus on the experience in the United States appreciating that there are salient differences in other jurisdictions.

Although some of the enumerated challenges are unique to deep brain stimulation, much of the critique is generic and could be applied to other areas of device regulation where methods derived from pharma are applied without a thorough appreciation that devices are different from drugs and that the regulation of one sector cannot be utilized on the other without potentially adverse consequences. It is concluded that the advent of personalized medicine may help bridge the regulatory gulf separating devices and drugs.

Drugs, Devices, and Difference

If we are to assert that devices and drugs each require a distinct brand of regulation, it is important to delineate the differences between these therapeutic modalities. Let us start with therapeutic impact and how efficacy relates to cost and prevalence. In general, drugs cost less and have a wider population impact than devices which have a higher start-up capital versus operational cost which may limit dissemination, even though cost-effectiveness analysis reveals that DBS in Parkinson's disease is competitive with pharmacotherapy in a European context (Valldeoriola et al. 2007).

From a revenue standpoint, the low unit cost and broad dissemination allow a drug to be considered a success if it has a small effect on a large number of people. While drugs like antibiotics have a low cost and have dramatic and immediate effects, most of the pharma marketplace is now composed of modern-day agents that address the threats of chronic disease illness. These are not the "miracle cures" or "silver bullets" of yore, but drugs like cholesterol-lowering statins or antihypertensive agents, which generate revenue on a daily basis, one pill at a time. Expectations for these drugs are tempered because their action is not the cure of disease but rather its prevention or amelioration, pushing back the threat of chronic diseases like heart disease or hypertension.

Expectations and revenue streams are quite different for devices which have a high unit cost. DBS electrodes and insertion can cost over $50,000. Given this, to be considered a success and market worthy, their expected impact has to be larger for each individual and more immediately apparent. A quick and significant therapeutic payoff is the marker of success because far fewer devices will be implanted than drugs and because the cost of the device – and its surgical implantation – exceeds the routine cost of drugs. In addition, because all the costs are front loaded, there is the expectation that the treatment effect will come quickly and be more surgical than medical, that is, large and immediate versus incremental and delayed.

Put another way, most drugs are rather utilitarian having a small effect on a large number of people over time. In the aggregate they positively affect the public health by reducing heart disease or stroke, as in the case of lipid-lowering agents or blood pressure drugs. (Conversely, over time, their societal misuse can have an adverse effect in the aggregate by prompting antimicrobial drug resistance with an ecosystem (Fins 1995)).

Devices are more personalized in their scope and impact. They are deployed less frequently. Although there are cogent medical and ethical arguments for their early deployment (Synofzik and Schlaepfer 2011; Schuepbach et al. 2013), historically they have generally been a treatment of last resort, to borrow a phrase from the late Jack Pressman who wrote a seminal volume on the early history of psychosurgery (Pressman 1998). In a twist on the usual way we think about genomic-/molecular-based "personalized medicine," deep brain stimulators are quite personalized, tailored to both the biology of a specific neuropsychiatric malady and the *particular* anatomy of a specific patient. Hence, a very major difference between drugs and devices is their delivery systems. Save for specialized infusions and personalized medicine, mass-produced drugs come from the pharmacy and are taken with a glass of water. They are standardized and come with expected bioavailabilities.

Devices, in contrast, require the intervention of a highly skilled surgeon as well as the expertise of an interdisciplinary team to program the device (Fins et al. 2006), *personalizing* both the assessment of the patient, the insertion of the device, and its manipulation. While medical/pharmacological interventions can require similar skill, the potential variance of effect based on surgical placement and device programming makes this a more personal engagement than pharmacology alone.

Moreover, the presence of the surgical intermediary, essential to device delivery, also is an important regulatory issue. It puts the surgeon in a central role both for his or her technical expertise and a purveyor of goods and as a purchaser. In the context of devices, the surgeon who implants the device becomes a consumer, if not in actual practice when his or her hospital purchases devices, then due to the influence that can be wielded to direct institutional purchasing.

The intimacy of this market, surgeons and vendors, also creates the opportunity for conflicts of interest (Fins 2007), marketing outreach, and research support that, at least in the case of spinal implants, has drawn investigations and Congressional scrutiny and serious concerns about impropriety and conflicts of interest (Armstrong 2008; Abelson 2007). As yet, this scandal has not breached the tentorium and the realm of DBS, but the context for its entry is there and worthy of concern and heightened oversight (Fins and Schiff 2010).

The nature of the small market also creates the opportunity for monopolistic practices and favoritism. The small number of device manufacturers can limit open access to devices for clinical trials because the industry favors those surgeons who are high volume users of their devices. This limits access to other investigators, either by withholding products or by denying "rights of reference," information about a device that an investigator would need to make an application to the FDA for study approval. Without this technical information, there is no way to submit, much less be approved, for a device trial (Synofzik and Schlaepfer 2011; Fins 2007, 2010).

This is more than a semantic point because these devices differ from drugs as a tool of inquiry. It is asserted that deep brain stimulators, unlike drugs, are *probative* as a means to discovery as they are therapeutic agents (Fins 2012). At this early juncture in their development, and our understanding of the therapeutic potentiality of the circuitry of the brain, all DBS work, approved as in the treatment of refractory

Parkinson's disease or not (Bronstein et al. 2011), remain ripe for the cultivation of scientific knowledge. This is quite distinct from the use of an "approved" drug whose utilization represents the culmination of a step-by-step sequence through an experimental process resulting in an agent that becomes a vetted therapy.

The sequence of drug discovery, in contrast to devices, is also laid out and its steps are understood. How we come to understand the circuitry of the brain and its therapeutic potential and its role in pathogenesis is far less stereotyped. In drug development the approach has become formulaic. Phase I trials demonstrate safety. Phase II studies demonstrate benefit and Phase III protocols show that the new agent is as good or better than the standard of care either in their therapeutic effects or an enhanced side-effect profile. The more recent Phase IV seeks post-marketing data for evidence of late-breaking side effects or toxicities, not apparent in earlier stages of assessment.

Although some "best practice" device trials have utilized the "Phase I–IV" demarcations (Laxton et al. 2010), this is far less universal than its usage with respect to the evolution of drug trials. And when such designations are used, they are simply derivative from the experience with drugs and pharma. Devices do not have their own schema, notwithstanding the occasional invocation of the phase milestones to studies.

Indeed, no such generally agreed-upon sequence exists for devices, making for confusion on how to move along a bright idea from bench to bedside and clearly demarcating the assessment of safety and efficacy. And the reason no clear sequence exists is because the use of DBS remains highly experimental and contingent upon the interplay of device (whose actions are predictable) and soma (which is variable dependent on anatomic locale, disease state, and programming of stimulation parameters) (Fins 2004). More fundamentally, the use of DBS remains fundamental to garnering information at the frontiers of human knowledge. The use of these devices is not yet ever exclusively therapeutic but always in part investigational elucidating the circuitry of the human brain and our ability to harness it or redirect it in the pursuit of health and well-being (Fins 2012). To view DBS, or much less regulate it, solely as a therapeutic device is to rob the work of its investigational potential, a potential that does not reside in most drugs approved by FDA.

And this leads to the final and perhaps most critical dissimilarity between the regulation of drugs and DBS, the role that intellectual property transfer plays in sustaining and promoting innovation. In the United States, intellectual property (IP) exchange between industry and the academy is governed by the Bayh-Dole Act of 1980, legislation that allows the rights to federally sponsored research which results in IP to be transferred from the US Government to the University where the pioneering work was done (Bayh-Dole Act 1980). The premise behind the law was that IP exchange to an interested and incentivized party (the University with its faculty investigator) would expedite negotiations with industry and accelerate the process of moving innovation from bench to bedside. And universities holding IP would be in a position to negotiate with industry because drug development could not go forward without pharma

owning the IP. In the aggregate this exchange of IP would bring new drugs most quickly to those in need.

In theory, and indeed in some quarters in practice, this legislation has fostered innovation. But in the context of DBS devices, it has, in my view, hindered progress by commodifying IP and giving it a monetary value too early in the course of development (Fins 2010). This is problematic because this commodification burdens the investigator with a putative conflict of interest that can preclude, under some guidelines, frontline research, research that they are most likely the best positioned to do. I suggested that IP transfer be delayed until after proof of principle in order to allow investigators most familiar with the work to get their studies through this pivotal early stage without placing a valuation on their ideas (Fins 2010).

This is suggested, in part, because of conflict of interest policies which might preclude investigator participation if there is a monetary conflict of interest. For example, the American Association of Academic Medical Centers (AAMC) has suggested that a "rebuttable presumption" governs academics' conflicts of interest (AAMC 2003). Under this presumption, investigators who have a significant conflict of interest are presumed *not to* be allowed to do clinical studies until the presumption has been reviewed and reversed by an institutional conflicts of interest committee.

In the AAMC recommendations on conflicts of interest, we see the divergence of drug versus device regulation in stark relief. First is the question of execution. In a drug study, one does not need the expert biochemist to do a drug trial to see if a compound that worked in the lab will work in vivo. It is quite a different story with DBS when a team of investigators needs to apply selection criteria, choose suitable subjects, *and* then operatively insert and then program a device. That is a set of skills that remain at the forefront of investigational work and cannot effectively be delegated to others before proof of principle has been established (Fins and Schachter 2001; Fins 2008).

Second is the issue of discovery. In most drug studies the mechanism and the biology of the agent have been worked out before a trial has begun. It is quite the opposite in the context of DBS where the trial itself will reveal information which can be pivotal for both current and future studies. To regulate such trials as if they were solely exercises in optimizing therapeutics fails to contextualize them against the great possibilities of discovery of biological mechanism is to misconstrue their importance and potential (Fins 2012). Thomas Insel, director of the National Institute of Mental Health, said it best when he stressed the importance of understanding underlying mechanisms of brain-based disease and pathology and supplementing theoretical information with biological data. He presciently noted that "Despite the importance of wiring diagrams, [they] like the original genome maps, are necessary but not sufficient for understanding how the brain works" (Insel 2011). Insel's focus on basic biological mechanisms and their importance to further discovery cannot be stressed enough, but regrettably the current regulatory structure under which DBS studies are being conducted does not facilitate such discovery. More often than not, the regulatory schema is

a pathway to market and a roadblock to discovery. This shortcoming of regulation – and industry's response – can be best seen if we turn to the recent controversy over the FDA's approval of DBS in the obsessive-compulsive disorder under the *aegis* of the Humanitarian Device Exemption (HDE) (Fins et al. 2011c).

HDE for DBS in OCD: Regulatory Challenges

In February 2009 the FDA "approved" the use of DBS for the "treatment" of the obsessive-compulsive disorder (OCD) under the rubric of a Humanitarian Device Exemption (HDE) (FDA 2009, 2010a). The HDE approach was in lieu of the more conventional IDE (Investigational Device Exemption) route to market in which both safety and efficacy as demonstrated via a properly powered clinical trial must be demonstrated (Peña et al. 2007). HDEs operate via a lower standard of evidence requiring evidence of safety and do not require a clinical trial's evidence of efficacy for approval. This lower standard is meant to facilitate approval of devices that are intended for "orphan" markets where the disease, as verified by the FDA Office of Orphan Products Development, verifies that the condition annually affects 4,000 or fewer patients. If the disease meets these criteria, the device manufacturer can apply for the HDE from the Center for Devices and Radiological Health at the FDA (FDA 2010a, b). And if the approval is granted, FDA approval fees are waived.

Previously, along with colleagues from the Deep Brain Stimulation in Psychiatry Working Group of the *Europäische Akademie* and the *Universitätsklinikum Bonn*, I made the argument in *Health Affairs* that the FDA's approval of DBS for OCD was inappropriate (Fins et al. 2011a, c). Beyond contesting epidemiological data that the target population was less than 4,000 patients per year (Fins et al. 2011c; Kessler et al. 2005; Pallanti and Quercioli 2006; Hollander 1997), we asserted that the use of DBS in OCD was not amenable to the less stringent HDE pathway because the use of the stimulator was not merely an analogous use of a previously approved stimulator, which it was, but rather a novel application for the device with insertion into a new site, in a distinct disease condition. As such, we argued that it was a new application that required the use of the more stringent IDE application (Fins et al. 2011c).

And we made this argument for two reasons which illustrate my central thesis that approval of devices, as if they were pharmaceutical agents, will create logical misconstruals and that devices require their own, not as yet, fully articulated ethical and regulatory framework. First, in the FDA approval, there was a near exclusive focus on the device and not the context of its use. Second was the failure to appreciate that the manner of the device's approval had implications for therapy and research.

Let us start with the premise that because the device had been approved in one set of circumstances, such as its prior use in Parkinson's disease (CMS 2003), it should also be approved in the context of OCD. After all, the stimulator and its mechanics and electronics are known to be safe, so why not assert that the device was safe, much like one might assert that the pharmacology of a drug developed for

one purpose could be used off-label for another. We speculated that FDA's "familiarity with the device might have distracted them from seeing the novelty of the brain target and clinical indication as the key reason why an IDE was indicated as the preferred pathway to market" (Fins et al. 2011b).

That leap of logic from the world of drug development, pharmacology, and drug metabolism just does not work in the context of DBS where the functioning of the stimulator is but a part of the equation. Here, both safety and efficacy hinge on the placement of the electrode as a well as stimulation parameters which can themselves have variable impact based on settings and how those settings evoke biological effects in *a particular locale in the brain in a particular disease state*.

Approval by analogy to the use of the same device in a different context also fails to take account of what might be learned if the placement is done for a different reason, for a different disease. Beyond the therapeutic benefits which might accrue, basic knowledge might emerge from aggregating data from such implantations. Unfortunately, this is impossible when the placement is done under an HDE because one cannot generalize data from individualized cases implanted off protocol (Schlaepfer and Fins 2010). This is a lost opportunity for discovery and speaks to the FDA's regulation of DBS in OCD as if it were the regulation of a vetted therapy and not the investigational work that it remains (Fins et al. 2011c).

This confusion is revealed in FDA regulations concerning the HDE which requires that an HDE approval be reviewed by an Institutional Review Board (IRB), bodies charged with the oversight of research ethics within an institution in the United States. Yet paradoxically, even though IRB approval was required, FDA does not require that *research consent* be obtained. From their point of view, FDA views the insertion of a device under the aegis of an HDE as the practice of medicine (Hurley 2011), although it cannot explain why the practice of medicine should, in any fashion, be under the jurisdiction of an IRB (FDA 2006; Fins et al. 2011b).

FDA's HDE approval of Medtronic's "Reclaim" device for DBS in OCD (Medtronic 2009) was readily marketed by the company as a therapy even though no efficacy data had gone into that approval (Fins et al. 2011c). In advertising materials promulgated by Medtronic, the company "...announced today its official entrance into psychiatric therapies with approval from the U.S. Food and Drug Administration (FDA) for a humanitarian device exemption (HDE) for its Reclaim™ Deep Brain Stimulation (DBS) Therapy for chronic, severe obsessive-compulsive disorder (OCD).... Medtronic plans to make Reclaim DBS Therapy for OCD available in the United States by mid-2009" (Medtronic 2009; Dooren 2009). This was ethically problematic because it implies that a device is therapeutic prior to subjecting it to trials of efficacy, thus fostering the potential for a therapeutic misconception on the part of those who might receive the intervention (Lidz et al. 2004).

Economics, Market Scope, and a Proposed Remedy

Ultimately, the greatest consequence of regulating devices as if they were drugs is that the expectations of drug regulation are placed upon devices when the resources

required to achieve that degree of regulation are not in place. Given the aforementioned size of pharmaceutical houses as compared to device makers and the relative size of their respective markets, the expectation that a full-fledged IDE – the device analog of an IND (investigational new drug exemption) (FDA 2011) – can be mounted for novel DBS applications may be misplaced. According to my own experience with a DBS trial in the minimally conscious state (Fins and Schiff 2010; Schiff et al. 2007), and sources from within the neuropsychiatric DBS-investigative community, resources for an IDE trial are tenuous and very often nonexistent. This leads investigators to attempt to do their research in suboptimal ways, such as resorting to the HDE option.

The pressures of developing a highly capitalized device for a small market are captured in the practices of the Medtronic Corporation as noted by Daniel Bernard. In a review of how the company utilizes the humanitarian device exemption process to build upon its previously approved devices in order to develop – or in many cases rebrand – old tools for new purposes, Bernard (2009) reports how predicate devices approved for use in Parkinson's disease become the platform for additional devices, utilizing a "horizontal model" of product development. Bernard (2009) notes that "...an undisclosed source at Medtronic claimed that it would have been too costly and time-consuming to obtain a premarket approval for their Humanitarian Device Exemption-approved Activa Deep Brain Stimulation devices.... Medtronic saved 3 years, recovered $10 million from the initial research and development costs, and established a good relationship with many physicians within the field."

If DBS is both a clinical tool and a tool of discovery, it will be in a no-man's-land between commercial and governmental funding. It is quite possible that it will be abandoned by the market, which will see it as investigational and think it the responsibility of funders like the NIH. The NIH might look at its commercial success in the context of Parkinson's disease and view it as applied, not basic, science. In either scenario, the work will suffer.

So how might the regulatory system be reformed within budgetary constraints? In addition to reform of the Bayh-Dole Act and changes to the timing of IP exchange to broaden the scientific commons suggested elsewhere, (Fins 2010), another suggestion previously outlined would be a new regulatory pathway intermediate between the IDE and HDE, namely the *mini-IDE* (Fins et al. 2012). The mini-IDE would be able to address both safety *and* efficacy utilizing limited resources. In lieu of ill-fated attempts to use the HDE as a way to do (bad) science or enter the marketplace hamstrung without resources to enable work via the IDE pathway, the mini-IDE would seek to bridge the gap between bad science and good (or better) policy.

The mini-IDE would start with a predicate approval of a prior device, much as is currently used when an HDE application is being vetted (or like the 510(k) approval process used in lower risk Class II devices (Committee Public Health 2011)). This approval based on safety data would be necessary but not sufficient and would therefore result in *contingent* licensure. This would need to be maintained over time meeting progressive standards approaching the more rigorous IDE. To move from contingent licensure to full approval, the device and its target would be subject to participation in a standardized hypothesis-driven trial as in the IDE process.

Mini-IDE data would however be generated differently than that obtained from the generic IDE process. Instead of collecting all the data in a single, time-limited, and capital-intensive trial, data for the mini-IDE study would be disseminated over time and space. The data would be generated over time under the rubric of contingent licensure and could take years to accrue to meet a statistical standard of efficacy. And once that standard was reached, the mini-IDE trial would graduate, as it were, and have the data necessary to be viewed as an IDE, allowing for approval under that more rigorous pathway.

The study would also be geographically dispersed and performed by different investigators, one at a time, much like current practice with the HDE. The key difference would be that to be eligible for the required contingent, mini-IDE licensure, investigators would have to agree to abide by a single centralized protocol that would allow for the pooling of results, outcome data, and adverse events. Data and a data-safety monitoring board would be centralized – we previously proposed that this might be a role that the Foundation for the NIH (FNIH) might play (Fins et al. 2012) and that a study registry be created to allow for data mining and the development of properly powered scientific analyses of safety and efficacy (Schlaepfer and Fins 2010; Synofzik et al. 2011).

The advantage of the mini-IDE schema is that it would allow hypothesis-driven work to proceed with limited resources and allow for the collection of aggregate data and the pooling of adverse event information which might have material value when viewed outside of the context of individual patient "studies." Pooled analysis would make both implicit toxicities more evident and potentially suggest novel therapies based on unanticipated "side effects."

Fiscally, the dispersion of the trial in time and space amortizes the cost. It would allow work to proceed without all the upfront capital expenditures that are necessary for an IDE. It would also maintain access to the benefits of studies like the HDE while providing the added benefit that study participation would result in generalizable data, something that would be impossible under the HDE approval process. And as importantly, the contingent licensure reminds the patient and the investigator that the device is still not a fully vetted therapy and thus helps to mitigate the challenge of the therapeutic misconception.

DBS as Personalized Medicine

Earlier, it was asserted that the placement of a deep brain stimulator was more akin to personalized medicine than conventional drug development. Instead of drugs produced for the masses, the insertion of an electrode into a particular brain in a highly personal matter must take account one's anatomy, physiology, and in the case of more experimental applications, as in traumatic brain injury, the lesions of an injured brain. For example, in Parkinson's disease, the target is chosen very individually. Sometimes it is the subthalamic nucleus (STN), the globus pallidus interna (GPi), and sometimes (in subjects with freezing of gait) the STN plus the substantia nigra pars reticulata (SNr).

In this way, this emerging therapeutic is much like personalized medicine where a drug is tailored, indeed developed to the illness of a *particular* patient. It is highly particularized and personal, targeted, and precision therapy designed to correct, override, or protect the individual against a deranged DNA sequence somewhere in the patient's genome. The ethical and regulatory challenges posed by this approach to therapy will not be fully articulated until we have more experience with personalized medicine (Soden et al. 2012). Nonetheless, some commentators have begun to point to the tension raised by drugs developed for individuals and not for the masses (Maglo 2012), a line of argument which echoes the dynamic between the regulation of drugs for the many and devices for the few.

That the same problem is now being confronted within the sphere of "conventional" versus "personalized" medicine suggests that the discordance between the FDA's regulatory approach to drugs versus devices is reemerging in a different and perhaps more powerful guise. And given the therapeutic power of this approach, regulatory issues will need to be identified and addressed.

As drugs become more personalized in design and scope, they will begin to resemble the nature of interventions like deep brain stimulation which have been, as noted, poorly regulated through the explantation of methods better geared to the oversight of mass-produced drugs than tailored therapies. Like devices, approaches to personalized medicine will be costly, personalized, and often idiosyncratic providing a therapy to some and knowledge of biological mechanism to others. Others might benefit from the new knowledge of a biochemical pathway elucidated through personalized medicine much as patients with brain injury are benefiting from the identification of the *mesocircuit* as a substrate of consciousness (Schiff and Posner 2007; Schiff 2010), a discovery made possible – in part – by work utilizing deep brain stimulation in the minimally conscious state (Fins 2012).

This generalization of knowledge from N = 1 cases shows that the personalized approach may be either therapeutic or probative. It also illustrates that a new method of oversight must come to the fore that allows discovery to proceed even as therapeutics emerge. As we saw earlier, the Humanitarian Device Exemption did not and could not achieve these dual goals. Novel approaches, such as the suggested mini-IDE, might prove an interim remedy to the challenges encountered in regulating and – as importantly – sustaining discovery through DBS.

Conclusion

The advent of molecular personalized medicine, to complement practices which have long existed in deep brain stimulation, will help motivate regulators to formulate new approaches to oversee the development of treatments for the few which might benefit the many. Now that DBS has an analog in personalized medicine, the problem of proportionate regulation becomes a shared one. It is an

urgent challenge to which all must attend, if progress is to be sustained in all realms of personalized medicine.

Deep Brain Stimulation Research Ethics: The Ethical Need for Standardized Reporting, Adequate Trial Designs, and Study Registrations

Abstract

The applications of deep brain stimulation (DBS) are rapidly increasing and now include a large variety of neurological and psychiatric diseases, such as addiction, Alzheimer's disease, anorexia nervosa, and rare movement disorders. High-quality data about benefit and harm of DBS in these disorders remain rare as many findings rely on small cohorts or single cases, variable methodologies, and differing outcome measures. Collectively, these problems make the field prone to bias and selective reporting, evoke ethical concerns regarding possibly premature expansions to new conditions without appropriate justification and research, and indicate the possibility that media, the public, and institutional review boards might be easily misguided by some reports. Thus, these problems are primarily not of scientific or methodological nature, but of *ethical* nature. Here, three approaches are suggested on how these problems might be reduced: by an optimization of trial designs, the implementation of

standards of reporting, and the creation of a DBS study register which includes in particular single-case studies or case series. Future work has to work out these proposals in more detail and study its effectiveness when implemented in practice.

Introduction

Randomized clinical trials (RCTs) and clinical experience have demonstrated that deep brain stimulation (DBS) is a powerful tool in the treatment of movement disorders like Parkinson's Disease (PD), Essential Tremor (ET), or dystonia. In the last years, these observations were complemented by promising results from small cohort studies of DBS in treatment-refractory patients with neuropsychiatric diseases like obsessive-compulsive disorder (OCD), major depression (MD), or Tourette's syndrome. Based on these experiences, the applications of DBS are now rapidly spreading all over the world to novel applications in patients with other neuropsychiatric diseases or rare movement disorders. There are first preliminary results reporting an effectiveness of DBS in case series of patients with anorexia nervosa (Lipsman et al. 2013), obesity, violent behavior (Franzini et al. 2005), minimal conscious state (MCS) (Schiff et al. 2007), alcohol addiction (Muller et al. 2013), Alzheimer's Disease (Laxton et al. 2010), or rare movement disorders (e.g., chorea acanthocytosis (Li et al. 2012), ataxia with abetalipoproteinemia (Mammis et al. 2012), or neurodegeneration with brain iron accumulation (Castelnau et al. 2005)) (for an overview, see (Hariz et al. 2013)). This rapid spread evokes strong ethical concerns regarding the possibility of premature expansion to new conditions without appropriate justification and research. Moreover, it might be seen as in indirect indicator of a widespread acceptance and usage of neuropsychiatric and movement disorder DBS before adequate safety and efficacy data are obtained. This possibility is worrisome in particular as DBS is not only rapidly moving toward novel indications, but also from larger specialized academic hospitals to smaller centers and even private practice (Bell et al. 2009).

In the early phase of its scientific investigation and clinical application, each novel DBS application is associated with the following problems:

– Limited evidence about the effectiveness of DBS (as RCTs will be lacking in the early stages of investigation)
– Small subject numbers, including only a single or a few patients
– Use of different outcome measures and variable methods of assessment within and between academic centers
– Reports with largely varying degrees of methodological and scientific quality

These problems are certainly not specific to DBS research, but apply to research in many other novel biotechnological domains as well (Clausen 2009). Thus, many of the ethical approaches already developed in the field of research ethics might be applicable to DBS research as well (for a general overview, see ▶ Chap. 70, "Human Brain Research and Ethics"), yet they need a DBS-specific articulation and specification (Clausen 2010). This is urgently needed in the field of DBS

since – despite the aforementioned problems – there is a tendency to rapidly accept apparently positive results from novel DBS applications and extend its usage. This can currently be observed with respect to DBS in some rare movement disorders or neuropsychiatric diseases (e.g., substance addiction) (Synofzik and Schlaepfer 2011). Importantly, the aforementioned problems are not only of *scientific* or *methodological*, but also of *ethical* nature.

– These problems a priorily constrain the possibility to validly assess the chances of benefit and risks of harm of a novel DBS application. This, however, is inevitably needed to determine the ethical criteria of beneficence and maleficence, which should be part of each ethical evaluation of DBS (Synofzik et al. 2012; Synofzik and Schlaepfer 2008, 2010).
– The excessive reliance on single-patient or small case series reports makes these nascent DBS domain highly vulnerable for selective reporting (Schlaepfer and Fins 2010; Synofzik et al. 2012). It opens up the possibility that only positive results (with often insufficiently controlled study designs) will be published, while negative data that might also have important implications will not be brought to the public (Schlaepfer and Fins 2010). Due to the inclusion of only one or few subjects, such small negative studies can easily be performed and analyzed without further attention by other researchers within and outside the respective centers. This well-known problem of selective reporting is already indirectly evidenced in the young field of neuropsychiatric DBS: several single-case studies have been published only because of interesting secondary effects, whereas the primary outcome effects were not achieved (Schlaepfer and Fins 2010). This indirectly indicates that there might be many other unpublished single-case DBS interventions for which the primary outcomes were not achieved and no interesting secondary effects were observed. Such a selective reporting will lead to a severe distortion of available evidence in this field which might harm future patients with neuropsychiatric disease or rare movement disorders (Dickersin and Rennie 2003).
– The above mentioned problems increase the likelihood that the reported scientific results are false positive or false negative with respect to the real outcomes. This will misguide other researchers, the media, and the public.
– They constrain the decision-making process of institutional review boards (IRBs) on the legitimacy of novel DBS studies and applications. Here, IRBs do not have a sufficient evidence basis to judge about the potential benefits and harms of a planned study. Moreover, IRBs might have to rely on potentially misguiding single-case reports and false positive or false negative small cohort studies for their decisions.

Thus, it is primarily not (only) a scientific, but an *ethical* necessity to call for a more rigorous methodological quality of DBS studies, comprehensive standards of DBS outcome reporting, prevention of selective reporting, and safeguards constraining a premature spread of DBS to novel applications and less experienced centers. This is of particular importance in the rapidly emerging field of DBS where many novel applications include children and/or complex neurodegenerative and neuropsychiatric diseases. Despite these obvious ethical needs, investigations

primarily focusing on the ethics of DBS research and reporting are still rare. Here suggestions for optimal trial designs, standardized reporting, and study registrations are outlined which might reduce the ethical problems outlined above.

Optimal Trial Designs

What level of evidence should be optimally used to establish safety and efficacy before a novel DBS application can move forward to clinical application? This complex question cannot be addressed here in full detail, but from an ethical perspective, it seems obvious (and almost trivial) to ask for randomized controlled trials (RCTs) as only they can establish true efficacy and rule out possible confounding factors. Depending on the expected effect size, RCTs are possible even for cohorts of <20 subjects. Even if a standard RCT would not be possible due to inadequate power, for example, in rare movement disorders, there is still a large variety of different trial designs that can be used to yield a randomized, comparative clinical trial (Cornu et al. 2013).

It is more difficult to determine the ethically most appropriate control condition. An active-controlled study design resorting only to best medical treatment (i.e., pharmacotherapy and/or behavioral therapy) does not completely suffice, as it could not rule out placebo responses to DBS insertion and/or DBS programming and would thus not allow making a final decision about the quality of DBS. An active placebo-controlled design, resorting to sham-stimulation (e.g., 0.0 V or subthreshold stimulation) and comprising, interalia, of surgery, electrode insertion, and parameter setting, seems to be the only way to control for such placebo effects (for an overview on sham surgery, see ▶ Chap. 72, "Ethics of Sham Surgery in Clinical Trials for Neurologic Disease"). Requesting such an optimally controlled study design is not just a scientific, but also an ethical demand: if DBS trials would refrain from using active placebo, DBS treatments might be approved, which appear more effective than standard treatments, but are, in fact, no more effective than placebo (in this case, sham-stimulation). This would lead to unjustified risk of harm for patients treated with DBS and to high, unnecessary intervention costs for the health care system. The feasibility of DBS sham-stimulation has already been demonstrated in a large-scale study in dystonia patients (Kupsch et al. 2006), in a smaller study in OCD patients (Mallet et al. 2008) and was also exemplarily investigated in patients with depression using off-on-off-on trials of varying short periods as well as a blinded discontinuation phase of 4 weeks (Mayberg et al. 2005; Schlaepfer et al. 2008). After a limited, well-defined study period, patients from the sham-stimulation arm should receive active stimulation.

This trial design is almost ethically innocuous, because patients are not asked to forego, but only to delay treatment of presumed benefit. Thus, the chance of presumed benefit might equiponderate the nontrivial risk of harm of DBS surgery (Synofzik and Schlaepfer 2011), which these patients have gone through. This design also prevents exploitation of the placebo-study arm for research purposes, because patients' participation confers presumed benefits not only to future patients

and society from generating biomedical knowledge (beneficence in clinical research) but also to the individual patients themselves (beneficence in clinical medicine). Importantly, the shift between sham-stimulation and active stimulation does not necessarily need to be performed within a double crossover design (AB/BA design) as this would mean that patients might experience major exacerbation of the underlying disease if effective active stimulation was substituted by ineffective sham-stimulation. In fact, a study of DBS in major depression has demonstrated that an AB/BA design might lead to such ethically highly problematic consequences and, subsequently, its cessation (Bewernick et al. 2010). Thus, it might suffice if only one study arm crosses from sham-stimulation to active stimulation (AA/BA design), i.e., the trial would follow a randomized controlled study design with *delayed start* of the control group.

Standardized Reporting

As already proposed earlier (Synofzik and Schlaepfer 2011), guidelines are needed not only for optimal *application* of DBS (including presurgical assessment, surgery, and long-term monitoring of DBS), they are also needed for ethically sound *publishing* in the field of DBS. Standards and guidelines of scientific reporting will lead to an improved quality of reporting (Coultas 2007). This, in turn, will lead to a better communication of the results to the public and the media as well as to a better evidence basis from which beneficence and maleficence can be evaluated within ethical analyses by IRBs, researchers, and clinicians.

In addition to the general standards of scientific reporting (CONSORT Standards [Consolidated Standards of Reporting Trials] (Moher et al. 2001)), the standards for DBS reporting should include several additional specific aspects.

1. The reported outcome parameters should include a detailed description also of the (long-term) side effects. It is now known from studies of long-term effects of DBS in both Parkinson's Disease (see ▶ Chap. 35, "Deep Brain Stimulation for Parkinson's Disease: Historical and Neuroethical Aspects") and Essential Tremor that DBS might be effective in treating some motor features, yet that this "comes with a price" (Warnke 2013): even in experienced hands, it comes with a range of side effects like worsening of verbal fluency and development of gait ataxia and dysarthria, respectively (Warnke 2013). These side effects will only come to the fore if they are searched for in detail and if long-term effects are responsibly reported in the public.

   Moreover, the reported outcome parameters should include not only symptom-specific or functional outcomes (e.g., changes in a disease-specific symptom score), but also outcomes that are meaningful in the individual daily life of the patients. This call for more comprehensive outcome reporting applies not only to DBS study designs per se, but also to follow-up assessments. They should integrate ***broader biopsychosocial outcome measures*** like reintegration into family life, social and work environments, and psychosocial and global quality of life. Moreover, to further improve assessment whether observed DBS

outcomes are truly beneficial or not, they should be complemented by ***qualitative measures***. This is necessary as changes in disease experiences, coping strategies, and psychosocial life situations are hard to capture by current (semi-)quantitative scales.

The need for such measures is illustrated by a study in PD patients (Agid et al. 2006; Schupbach et al. 2006): in spite of, or probably because of a clear improvement in various outcome variables after DBS implantation, many are not happier with their lives. They go through tormented periods in their marriages or fail to resume professional activities postoperatively. This experience of PD patients does not seem to be specific to that condition, but can be expected after rapid symptom modification in any chronic life-determining disease, psychiatric or somatic. For example, a rapid improvement of major depression, obsessive-compulsive disorder, or addiction will change previous personal activities of daily living and social relations in a more drastic and rapid way than can be compensated for by the individual himself/herself and by his personal surroundings. It was reported for a patient with PD and for a patient with MD that after "highly successful" DBS treatments, comorbid personality disorders came to the fore (Schlaepfer and Fins 2010). This effect seriously complicated the following treatment and reduced quality of life measures below the pre-DBS state (Schlaepfer and Fins 2010). These different experiences from different centers and different patient groups clearly indicate that merely reporting symptom-specific scores can be highly misleading with respect to the true net benefit for the patient. This can only be captured by more comprehensive outcome reporting.

The demand to report individually meaningful outcomes of daily living and quality of life beyond mere symptom-specific scores can already be applied to current studies. For example, in a trial of seemingly "successful" DBS for Minimal Conscious State (MCS), one might cautiously ask about the potential for incremental distress from increased self-awareness associated with cognitive improvement (Fins 2000). Even if the MCS patients would not suffer from increased mental distress, it remains questionable whether the improvements in vigilance are sufficient to lead to an improvement in quality of life.

The quality of life outcomes assessed within a study should not only be reported in the appendix, but in the main text of a report. A recent DBS case series of patients with anorexia nervosa (Lipsman et al. 2013) reported the quality of life outcomes only in the appendix. Interestingly, in this series, three out of six patients did not show improvements in quality of life (cf. de Zwaan and Schlaepfer 2013).

2. The scientific reports have to systematically report also ***all nonsurgical and nondrug therapies*** received by the study patients, both before and after DBS surgery. Any changes in these therapies might essentially contribute to the observed effects which might be prematurely related to DBS, in particular in neuropsychiatric diseases. For example, the additional care by a psychotherapist or its withdrawal, a change in the person of the treating psychotherapist, or a novel interdisciplinary counseling or novel expert therapy might lead to substantial effects that are not related to DBS, but, for example, to the

preoperative assessment in the course of DBS or simply to the change of the patient from an outside clinics and physician to a tertiary care center. If these preceding and subsequent therapies and the components of the therapies and the treatment team are not systematically captured and reported by the study investigators, the reported study effects are at risk to be (falsely) associated with the DBS insertion (in the intervention group) or non-DBS insertion (in the control group). This will lead to false positive or false negative results. For example, a phase 1 study on DBS in anorexia nervosa that was recently published in a high rank journal (Lipsman et al. 2013) did not report these therapies and the elements of the treatment team, let alone their continuation and discontinuation, respectively. This hampers, and potentially confounds, the interpretation of the overall results as well as single results. For example, it makes it hard to explain why subjects still gained more weight before surgery (2.4 body mass index [BMI] points) than they did afterward (0.5 BMI points), whether their postoperative weight loss (mean 2 BMI points) was really due to loss of enhanced in-patient care rather than an adverse effect of DBS surgery, and whether the eventual postoperative recovery from weight loss was really due to a DBS effect rather than increased intensive support after postsurgery weight loss (Hutton 2013).

Likewise, another case series of DBS in patients with anorexia nervosa (Wu et al. 2013) did not mention whether psychotherapy, which is considered the treatment of choice, was performed. This indirectly suggests that it was not applied at all. Thus, not reporting the nonsurgical therapies makes it difficult to decide whether the study did appropriately select and treat the subjects or not. If subjects did not receive the treatment of choice prior to DBS, they might have been undertreated prior to DBS. Moreover, if it is not reported whether they did or did not receive treatments according to the current guidelines (an information that was also omitted in the report by Wu and colleagues (Wu et al. 2013)), it cannot be decided if the subjects were adequately treated prior to DBS or not (de Zwaan and Schlaepfer 2013). It should also be reported whether or not the subjects received guideline-based treatments for their disease *after* the surgery (de Zwaan and Schlaepfer 2013). This fact – which was also not reported, for example, in the DBS study for anorexia nervosa by Lipsman et al. (2013) – might change the outcomes of the study. In addition, omission of a guideline-based treatment might also need particular ethical justification.

3. Scientific reports have to systematically include information about all the consequences of DBS in the psychosocial domain, in particular also in those ***patients where DBS was not effective***. This is important as, for example, in novel neuropsychiatric DBS applications like MD or OCD, a large share of patients does not respond to DBS – in several studies up to 50 %. These patients are often not of any further interest for the study investigators, whereas the patients where DBS was effective receive many further up assessments, counseling, and in-patient care within and outside of study protocols. Thus, it has to be reported whether and how ***follow-up care for DBS-negative patients*** was ensured, and which alternative care and treatment options (instead of DBS) were offered by the specialist center.

4. Scientific reports have to explicitly discuss whether the reported results are not only statistically significant, but indeed ***meaningful in terms of further treatment*** of the patients. Moreover, they should explicitly discuss the possibility whether they might lead to misinterpretation and possible misguidance of IRBs, media, and the public. Several recent uncontrolled observational DBS studies on single cases or small case series might have been correct in themselves; however, they remain vague and partly dubious about the question which consequences could by validly drawn for clinical practice. Thus, they opened the possibility to misguide patients, the public, and IRBs that have to judge on the legitimacy and adequacy of similar studies and of clinical application of DBS in this context. For example, a study on ten patients with DBS of the nucleus accumbens showed that three out of ten patients stopped smoking in the further course of the DBS treatment (Kuhn et al. 2009). A control group that would have received DBS at a different brain site, or surgery elsewhere at the body (e.g., in the abdomen), was missing. Thus, it remained unclear whether the (already relatively small) observed effect was a specific effect of DBS of the nucleus accumbens or might be expected also by DBS of other brain sites or even by any larger surgery with intensive presurgery and postsurgery care, and might thus be completely unspecific. The public, media, and IRBs might be prematurely inclined to accept the assumption that DBS of the nucleus accumbens would present a promising option in the treatment of tobacco addiction. Evidence for premature misinterpretations of study results by the media can be drawn, for example, from the report of DBS in anorexia nervosa (Lipsman et al. 2013). Even though the authors performed a careful interpretation of their study results, namely, primarily in terms of safety of the procedure, the general press interpreted the results very differently (de Zwaan and Schlaepfer 2013). Such a bias in media-reporting will be facilitated even more if researchers themselves do not discuss more explicitly whether or not their study results already imply clinical effectiveness, and if they do not explicitly discuss potential misinterpretations that might mislead the media and the public.

Study Registration

Even if DBS studies would follow an optimal trial design and the standards of outcome reporting, one problem remains: the current excessive reliance on single-patient or small case series in the field of neuropsychiatric DBS or of DBS for rare movement disorders. As outlined above, this trend makes the DBS domain highly vulnerable for selective reporting. It is of upmost importance of this nascent domain to know and share both positive and negative results of isolated studies and observations that would otherwise not be reported by the broader scientific community. Moreover, this trend leads to the fact that an important chance to share and aggregate data on efficacy and safety of DBS is still neglected.

To encounter these problems, a central registry for DBS was proposed (Synofzik et al. 2012). This registry is characterized by one important specific feature: in

contrast to a prototype registry like *Clinicaltrials.gov*, which does not include small feasibility and pilot studies of devices as well as single-case interventions, the eligibility of the DBS registry should not be limited only to rigorous clinical trials. Instead, in addition to established clinical trials, this registry should also include single-case DBS studies, clinical reports without control or comparison group, and isolated cases using human device exemptions (HDEs). Both interventional and observational studies would be accepted and trials should be registered irrespective of the anticipated or hypothesized outcome.

In addition to this prospective enrollment, retrospective clinical observations about DBS effects in neuropsychiatric patients can also be posted. This applies, for example, to relevant clinical or surgical anecdotes, important stimulation parameter findings (be they beneficial or detrimental) or interesting side effects (e.g., perioperative mood effects (Okun et al. 2007) or enhanced memory functioning (Hamani et al. 2008)).

But is such an effort really necessary? As described before (Synofzik et al. 2012), the key arguments supporting implementation of a specific DBS registry are mainly centered on patient safety and trial efficacy, yet they also serve many additional goals such as serving as a platform for data aggregation, regulatory oversight, and dissemination of innovative techniques (see Box 1).

For example, meta-analysis of pooled aggregate data from multiple small trials linked in a registry may demonstrate heretofore unrecognized efficacy in the fields of neuropsychiatric DBS or rare movement disorder DBS which are still marked by single-case reports and small cohort studies. Rather than a single case, it will be the body of evidence, aggregating many trials, that will have a persisting impact on medical practice (DeAngelis et al. 2004). Also information about adverse events can be aggregated and analyzed which might not be collected otherwise. This is of particular importance as it would not be possible for a patient or an IRB to assess the risks of participation in a DBS trial if an unknown proportion of adverse effects on the proposed intervention were not registered and not publicly available

Box1: Advantages of a DBS Registry in Neuropsychiatric DBS

- Accumulate beneficial effects
- Aggregate adverse events
- Collect long-term data
- Collect data on ineffective DBS/failed trials
- Give back the benefit of aggregated information to the patient
- Identify side effects that might serve as therapeutic effects
- Detect modifications of prespecified primary outcome measures
- Coordination of research trials and research groups
- Reduce idiosyncrasy in research and in IRB decision-making
- Provide orientation for IRB review
- Compensate for the shortcomings of early psychosurgery
- Attract industry funders

(Zarin and Tse 2008). If the DBS registry entails also post-intervention observational information covering periods of time longer than typically studied in controlled trials, it will provide an invaluable resource for longitudinal assessment of both efficacy and safety and the late unanticipated adverse event, as, for example, in patients with depression, where long-term data are currently still missing and often difficult to assess (Dunner et al. 2006). Such aggregation of information could provide benefits to trial participants who have agreed to participate in investigative DBS and who have placed themselves at risk not only due to the hope of personal benefit, but also due to the desire to increase generalizable medical knowledge (DeAngelis et al. 2005; Schlaepfer and Fins 2010).

A DBS registry could also serve as a repository for information that may not have ever been published but which might remain useful to the broader investigative community. For example, it would allow for the collection of ineffective DBS and help avoid a success bias which results from publication of only the efficacious studies. Knowledge of the failures as well the benefits will help avoid subject exposure to repeat studies that have already proven to be disproportionate and avoid the waste associated with repeating ineffective studies.

A DBS registry also allows to identify and aggregate information on DBS side effects which turn out to be therapeutic effects for comorbid features (e.g., remission of concomitant alcohol dependence in a case of nucleus accumbens DBS which primarily aimed at treating an anxiety disorder(Kuhn et al. 2007)). Moreover, it allows to detect modifications of prespecified primary outcome measures. Sometimes one study's adverse event becomes another's primary outcome (Schlaepfer and Fins 2010). For example, a case of unsuccessful DBS treatment of obesity was primarily published because of enhancement of memory states (Hamani et al. 2008). This point to the possibility that primary outcome measures might potentially be modified in the course of those DBS studies where the initial primary outcome measures are not achieved. If the primary prespecified outcome measures are posted in a DBS registry already at trial inception, such modifications can easily be detected.

Finally, a DBS registry could also serve an important ethical and regulatory role. It could help facilitate coordination of research trials by providing cross-center knowledge about past and ongoing studies and exert a moral corrective function through scientific consensus and common standards. By this means, it acts against possible idiosyncratic intervention and assessment standards and aberrant patient selection in single DBS centers across the world. By ensuring that all scientific centers adhere to a certain set of minimal standards, within and across center, variance will be decreased and less patients will receive unjustified harm.

Conclusion and Future Directions

It is primarily not a *scientific*, but an *ethical* necessity to ensure more rigorous methodological quality of DBS studies, comprehensive standards of DBS outcome reporting, prevention of selective reporting, and safeguards constraining a premature spread of DBS to novel applications and less experienced centers.

This is of particular importance with respect to those novel DBS applications that include children and/or complex neurodegenerative and neuropsychiatric diseases with highly vulnerable patients. Here we argued for a DBS research ethics program. As a first step, we illustrated the ethically driven need for optimal trial designs, common standards of outcome reporting, and registration also of single-case and small case studies. Future work has to work out these proposals in more detail and ensure and test their implementation in policy making, research, and clinical practice. So far, none of them have been put into practice.

Abstract

Over the last decades, deep brain stimulation has become an established treatment for movement disorder. However, the recent clinical research investigating the application of the technique for neuropsychiatric disorders as well as the potential to use DBS in a wider range of conditions has brought ethical controversy. This chapter examines some of the ethical objections against extending the use of DBS beyond the treatment of movement disorders. The first part of this chapter focuses on the objections related to the past uses of psychosurgery and examines the ethical weight of invasiveness and reversibility, two commonly used concepts in ethical discussions about DBS. The second part examines objections related to freedom and autonomy, including the slippery slope arguments related to "mind control," as well as the issue of control over the parameters of the stimulation in the context of cognitive liberty. The third part briefly discusses the objection to the enhancement uses of DBS, highlighting different contexts in which DBS can be used for enhancement while arguing for a systematic consideration of ethically relevant factors instead of the reliance on the treatment/enhancement distinction. The final part addresses the objection to DBS related to threats to identity. First, the ethical weight of discontinuity under psychological continuity approaches to identity is discussed. Next, the focus turns to the narrative approach to identity and Schechtman's objection to the use of DBS, and it is argued that although the narrative approach brings valuable insights, the normative conclusions we can draw from it are limited.

Introduction

Although deep brain stimulation (DBS) has been used to treat Parkinson's disease for some time (see ▶ Chap. 35, "Deep Brain Stimulation for Parkinson's Disease: Historical and Neuroethical Aspects"; ▶ Chap. 63, "Ethics of Functional Neurosurgery"; ▶ Chap. 29, "Parkinson's Disease and Movement Disorders: Historical and Ethical Perspectives"), recent decades have seen an increased focus on the potential of DBS as treatment for neuropsychological disorders such as major depression, OCD, and Tourette's syndrome (Holtzheimer et al. 2012; Krack et al. 2010). Preliminary research investigated the use of DBS for disorders of consciousness (Schiff et al. 2007; Yamamoto et al. 2010), Alzheimer's disease (Laxton et al. 2010; Smith et al. 2012; Lipsman et al. 2013), obesity (Halpern et al. 2008; Bauer et al. 2008; Kuhn et al. 2007; Lu et al. 2009), aggression (Hernando et al. 2008; Kuhn et al. 2008), and a handful of case studies reported post-DBS outcomes in neuroacanthocytosis and Huntington's disease (Edwards et al. 2012).

Some estimate that over 80,000 patients have already been treated with DBS and another 8,000–10,000 undergo stimulation each year (Lozano 2012; see ▶ Chap. 34, "Ethical Implications of Brain Stimulation"). The investigation of DBS for neuropsychological and neurological conditions is likely to increase. Yet, the prospect of extending the use of DBS to the treatment of depression, OCD, Tourette's

syndrome, and addiction, as well as the potential for enhancing interventions has led to significant unease and criticisms. This chapter critically reviews some objections to the use of DBS related to research ethics (the past abuses of psychosurgery, invasiveness), freedom and autonomy, as well as personal identity (psychological continuity and narrative approaches).

Psychosurgery, Invasiveness, and Reversibility

The Shadow of Psychosurgery: "DBS Should Not Be Used for Neuropsychiatric Disorders Because of Past Abuses in the Use of Psychosurgery and ECT in That Population"

DBS has developed in the shadow of past psychosurgery abuses, including the lobotomies performed by Moniz and Freeman and Heath's Tulane electrical stimulation program (Baumeister 2000; Pressman 1998). Moreover, dystopian images from works of popular fiction picturing brain interventions, such as *One Flew Over the Cuckoo's Nest* or *The Manchurian Candidate*, may influence the public perception of DBS (Schermer 2011). Although the current media reporting is mainly positive ("pacemaker for the brain" rather than "Brave New World," see Racine et al. 2007), there is a worry that DBS treatments will mirror the history of psychosurgery, with the initial hype leading to misuse and overuse subsequently replaced by controversy and abandonment of the technique (Hariz and Hariz 2012). According to Hariz and Hariz (2012), suggesting "that the technique be used for cognitive enhancement in non-pathological conditions, and even for alleged antisocial behaviour, are reminiscent of a dark era, and constitute a bad omen for the future of this technique."(p. e5477)

Many commentators acknowledge the history of psychosurgery but have distinguished the current incarnation of DBS from past uses, especially the misused application of lobotomy (e.g., Bell and Racine 2012). DBS is significantly more reversible, its settings are adjustable, the knowledge base supporting it is more solid, and it is performed in the context of different ethical and professional standards of practice, including the standards for patient selection, informed consent, and ethical oversight (for a systematic comparison, see Table 1 in Synofzik and Schlaepfer 2008). Others criticize the "clear-cut" approach to the history of DBS and psychosurgery, reinforced by some prevalent misconceptions (Hariz et al. 2010). While the "clear-cut with the past" narrative might protect DBS from unjust controversy and shallow comparisons, it might rob us of valuable lessons and come at the price of misrepresenting facts. On the other hand, while past questionable practices might give us a good reason to proceed with caution and carefully monitor DBS applications, they are not in themselves a good reason to halt the clinical research on novel applications.

Moreover, solely focusing on the history of psychosurgery in discussing the ethics of DBS brings three dangers. Firstly, shallow comparisons based on the invasiveness and past inappropriate use might trivialize the debate, while it is

necessary to carefully examine the reasons for the past misuses of psychosurgery, asking which aspects of those practices were and were not ethically problematic in order to see to what extent we have progressed since then (see ▶ Chap. 59, “Ethics in Neurosurgery”; ▶ Chap. 31, “Informed Consent and the History of Modern Neurosurgery”; ▶ Chap. 60, “Neurosurgery: Past, Present, and Future”; ▶ Chap. 36, “Risk and Consent in Neuropsychiatric Deep Brain Stimulation: An Exemplary Analysis of Treatment-Resistant Depression, Obsessive-Compulsive Disorder, and Dementia”). Secondly, we may overlook a host of different ethical challenges we face today, such as those related to distribution of scarce resources and proceeding with clinical research in a market economy with the strong and necessary involvement of the medical devices industry from the earliest stages of application. Thirdly, we might miss some more important and current comparisons, such as the more recent history of psychopharmacological agents and the underreporting of long-term side effects (see ▶ Chap. 38, “Deep Brain Stimulation Research Ethics: The Ethical Need for Standardized Reporting, Adequate Trial Designs, and Study Registrations”).

Intuitions About Invasiveness: “DBS Should Not Be Used for Neuropsychological Disorders Because It Is Invasive”

Reversibility and invasiveness of DBS are the two key words repeatedly used in both scientific and ethical papers about DBS. The gist of the use can be captured in one sentence: “Despite the fact that DBS is invasive (which is obviously bad), it is reversible (which is very good).” Although the two terms are commonly used as if their meaning was obvious, the root of their rhetorical power is somewhat more complex. Arguments against the use of DBS and calls for caution often include references to the invasiveness of the procedure. For example, Lipsman and colleagues (2011) pointed out that “[a]lthough DBS is [an] minimally invasive neurosurgery, it is the most invasive psychiatric treatment available” (p. 40). But what is the normative force of the concept and what could “invasiveness” refer to?

Firstly, “invasiveness” of the procedure might refer to a particular mode of crossing the skin boundary, as in the Merriam-Webster Medical Dictionary which defines “invasive” as one “involving entry into the living body (as by incision or by insertion of an instrument)” (“Invasive,” n.d.). Clearly, crossing the skin boundary is not in itself a good or a bad thing and a normatively rich concept of invasiveness refers to certain kinds of harm. In DBS, invasiveness points mainly to surgery- and device-related adverse events, including the risk of intracerabral hemorrhage, postoperative infection, and electrode displacement (Kuhn et al. 2010). Although invasiveness might point toward risks associated with the surgery, there are certainly procedures that are invasive in a technical-medical use of the word, and in ordinary circumstances not terribly dangerous (such as blood draw or biopsies). Thus, although invasiveness might point toward risk, it is not a clear normative guide.

The rhetorical force of the word “invasiveness” in the context of DBS is also rooted in several other sources. Firstly, it evokes intuitions about bodily boundaries,

such as those echoed in the emphasis put on concepts such as bodily integrity in the context of cadaver organ donation and a certain intuitive bias against surgical procedures. On the other hand, invasiveness might be a psychological concept and refer to the effects of the intervention on cognitive and affective processes and corresponding physiology. For example, psychotherapy might be considered to be noninvasive in one sense (does not involve incisions, etc.), yet invasive in the sense of changing thought and emotional processes, with associated physiological changes such as changes in brain metabolism. Moreover, invasiveness may refer to inappropriateness of a certain external influence – questions that cross the boundary of privacy might be called invasive and psychotherapy that does not take into account patients' views and wishes might be called invasive.

Neuromodulation techniques are sometimes, explicitly or implicitly, evaluated on the basis of invasiveness: the more invasive the neuromodulation technique, the less acceptable its use. Disguised as a straight-forward descriptive term referring to a kind of medical intervention but commonly used with strong normative undertones, the notion of invasiveness is a poor normative guide. Since the concept's rhetorical force comes from several separate sources beyond simply harms associated with surgery, it is important to be aware of how it is used.

Dilemmas in Patient Selection: "DBS Should Only Be Used as a Last-Resort Treatment"

Kuhn et al. (2009) note that there is a deep intuition, reflected in ethical guidelines, that an invasive procedure such as DBS should only be a last-resort treatment. Whether this widely stated conviction is justified is far from evident. It is one thing to emphasize the potential of DBS for helping patients with severe and otherwise irremediable disorder and prioritize early-stage clinical research to target this patient population on the basis of both need and risk/benefit ratio. It is a different, and a much stronger claim, to state that the procedure should *only* be tried when nothing else worked.

Since the emergence of the "access to experimental treatment" movement and an increasing consideration for patient treatment preferences and the recognition that patient's toleration of different kinds of risks differs, the protection of patients has ceased to be the only argument on the table. It is conceivable that in the not-so-far future, some subpopulation of patients might prefer to resort to DBS before trying all, many, several, or any of the available courses of different plausible pharmacological remedies (see ▶ Chap. 37, "Devices, Drugs, and Difference: Deep Brain Stimulation and the Advent of Personalized Medicine"). We might very soon be forced to decide whether to provide access to patients with a less impressive *résumé* of tried treatments. DBS plus drugs has already been suggested to be a better treatment option than the current pharmacological treatment for early motor complications in Parkinson's disease: Despite a higher rate of adverse events, the neurostimulation group had a higher mean score on a quality of life measure (Schuepbach et al. 2013). References to invasiveness and risk usually do not tell

the whole story and if we deny access, it is important to be clear about the reasons. Is it a matter of prioritizing the population with the greatest severity of symptoms? In the light of the troubled past of brain stimulation and surgery, is it a matter of protecting DBS from controversy to protect less controversial applications but at a cost of denying other patients access to a potential benefit? Is it prioritizing research on the population that is likely to achieve greatest symptom reduction and subsequently demonstrate the greatest efficacy of treatment?

Although it is sometimes easier to reach consensus about ethical guidelines than on the reasons for those guidelines, it is important that the reasoning behind the guidelines is made explicit. The strength of the rationale for those guidelines changes as the research progresses, and, as the consensus starts to dissolve, the transparency about reasons is necessary for the quality of our ethical discussion.

Intuitions About Reversibility

"Reversibility" is an often evoked concept, typically used to emphasize the comparative advantage of DBS over ablative surgery (e.g., Andrade et al. 2010; Greenberg et al. 2006). The intuition about the prudential and moral force of reversibility might be rooted in the intuition that ceasing an active intervention alleviates the associated harms. Prudentially, a risky intervention is seen as less risky if we can "undo" the effects. Ethically, one could hold a view that to reverse the effects of an intervention is to "wipe out" some of the moral implications of it: One is less morally culpable if the harm that was done is averted.

One of the concepts of reversibility refers to return to the *status quo ante* – back to the starting point. Yet, such understood reversibility does not wipe out all moral implications: Even restoring the *status quo ante* does not alleviate the moral weight of the harms (or benefits) already incurred.

Moreover, a comparatively lesser destruction of brain tissue does not necessarily equal nearly full reversibility of morally relevant effects. The reversibility of the intervention itself is not the same as the reversibility of the *effects* of the intervention. Firstly, the physiological and functional effects directly traceable to the effects of stimulation might be reversible only to some extent. The reports of a rapid increase in treated symptoms after the stimulation was stopped (e.g., after battery failure) could lead us to assume that all other effects are also reversible. However, this conclusion might be premature, especially in the absence of solid empirical data about long-term effects after discontinuation of treatment as well as the precedence of initially under-reported and overlooked side effects of pharmacotherapy (e.g., SSRIs), sometimes remaining for months or years after the treatment has been discontinued (Csoka and Shipko 2006).

Secondly, a patient's psychosocial situation might have changed. The patient might have spent a significant time adapting to a new state of being, developed new preferences and ways of living, lost the habits and environmental support that allowed them to cope previously, and developed a new set of strategies to compensate for a different profile of functional strengths and deficits. Thus, even if we

could know that otherwise the patient had returned to the exact same affective and cognitive state as she was in prior to DBS, the patient might be left in an even less advantageous position than prior to DBS. Naturally, the inverse is also possible – a patient might be in a generally better position to cope with the consequences of discontinuing treatment. The case in point is that the removal of the DBS electrodes does not entail returning to the starting point – the procedure is, in Synofzik and Schlaepfer (2011) words, "psychosocially irreversible" (p. 10).

While *the stimulation* might be reversible, it remains an open question to what extent *the effects* of the stimulation are indeed reversible, and it is the effects which are morally relevant. It might be better to regard DBS to be as reversible as marriage is – although one can *divorce*, it would be an exaggeration to say that marriage is *reversible*.

Freedom and Autonomy

"Deep Brain Stimulation Should Not Be used Because It Can Lead to Mind Control"

Extending the use of DBS can lead to worry about a slippery slope leading to "mind control." Although the dystopian image of externally controlled soldiers or prisoners forced to undergo DBS for behavioral control is indeed troubling, several intuitions seem to feed into the "mind control" worry. Firstly, one can object to the coercive use of DBS (see also ▶ Chap. 57, "Compulsory Interventions in Mentally Ill Persons at Risk of Becoming Violent"). Secondly, the worry might refer to the use of medical technologies for social control purposes (see ▶ Chap. 79, "The Morality of Moral Neuroenhancement"). Thirdly, we might see a difference between the use of coercion or a strong incentive aimed at a change in the sphere of the physical (e.g., interrogation techniques aimed at signing a declaration of agreement with the ideology X) and the mental (techniques aimed at brainwashing prisoners into believing in the tenets of ideology X). Physical coercion does not preclude retaining autonomy over one's thoughts and disobedience when an opportunity arises. As Mahatma Gandhi is thought to say: "You can chain me, you can torture me, you can even destroy this body, but you will never imprison my mind."

Further, we might perceive a difference between an indirect impact on the brain (manipulating one into believing X) and a direct one (using drugs or brain stimulation together with propaganda material to induce believing X). The perception here may be that while indirect impact can be modulated by beliefs, direct impact leaves less ability to modify the behavioral consequences. This is why, although DBS is subject to a similar dual-use problem as knifes and police force, the prospect of misuse of direct means of brain modulation and modification evokes especially strong unease.

The "mind control" objection relies on a slippery slope argument. Thus, the strength of the objection depends on what particular technologies are likely to do as well as practical matters such as comparative cost. For example, the prospect of a remotely steered individual performing complex actions is significantly more

far-fetched than using DBS for evoking undirected aggressive behavior or for remote disabling of movement. Even if the technology could be developed, it might be financially impractical to use DBS instead of stun guns and existing surveillance. Secondly, the strength of this objection depends on the balance and probability of harms and benefits, a factor perennially tricky to asses in dual-use dilemmas (see ▶ Chap. 116, "Biosecurity as a Normative Challenge"; ▶ Chap. 112, "Weaponization of Neuroscience"). The distribution of harms should also be considered. Coercive use of DBS for social control purposes is less likely to happen on any significant scale and without controversy in most Western democracies, but the situation may look different elsewhere. Thirdly, there is a question of whether halting the research and treatment would make a difference in the longer run in reducing the risk of misuse.

"Deep Brain Stimulation Should Not Be Used Because It Might Compromise Freedom"

Moreover, there is a wider issue of liberty with respect to one's thoughts and desires. Even if the overall consequences of DBS applied sparingly and mainly to a good social purpose, as Persson and Savulescu (2008) propose, we might not want to live in a society that overwhelmingly trades freedom for safety (Harris 2011).

Actions are subject to legal and moral prohibition, not desires and thoughts on their own. The freedom to do as we please in the domain of our mental life may be of particular importance (see ▶ Chap. 42, "Mind Reading, Lie Detection, and Privacy"). This is an underlying thought in Sententia's (2004) formulation of cognitive liberty:

> "*Cognitive liberty is a term that updates notions of 'freedom of thought' for the 21st century by taking into account the power we now have ... to monitor and manipulate cognitive function. Cognitive liberty is every person's fundamental right to think independently, to use the full spectrum of his or her mind, and to have autonomy over his or her own brain chemistry*" (pp. 222–223).

While the coercive use of DBS may compromise liberty, voluntary use of DBS might be regarded as simply exercising that liberty. It is a matter of discussion whether cognitive liberty is merely a negative freedom (freedom from interference) or a positive freedom (freedom to) and how strong an argument it provides for the access to relevant technologies. Moreover, there is a question of justifiable restrictions to cognitive liberty (see ▶ Chap. 32, "Nonrestraint, Shock Therapies, and Brain Stimulation Approaches: Patient Autonomy and the Emergence of Modern Neuropsychiatry"). Currently, this question arises in relation to access as well as the choice of stimulation settings.

Who Chooses the Settings?

The first question is whether one should have control over the stimulation and be able to adjust the settings out of the consulting room. Generally, patients can control

whether the device is on or off. Some choose whether the device is on or off depending on an activity (e.g., walking: on, talking: off), and some can also turn the device down during the night to save battery life (Mathews et al. 2011). Patients whose treatment influences mood might want to modulate their mood appropriately to the situation at hand. If DBS influences mood in more complex ways than just changing the baseline of positive/negative affect, control over settings might be necessary to experience specific valued moods. At the moment, there is no data on whether leaving the control of the stimulator up to the patient is beneficial or harmful (Mathews et al. 2011), although some have worried about excessive stimulation for hedonic purposes (Oshima and Katayama 2010). Regardless of harms and benefits, continuous control over the stimulation could be seen as an important way of exercising autonomy.

Secondly, during the adjustment of stimulation settings, patients and doctors may face a dilemma as to what level of mood improvement is optimal. What should happen if their opinions differ? The importance of a careful consideration of those questions is demonstrated in a recently reported case of a patient receiving NA (Nucleus Accumbens) stimulation for OCD and GAD. As the voltage increased, the sensation of being relaxed and hedonic experience increased, while at higher voltages, the patient began to feel "unrealistically good," "overwhelmed," and began to worry that the anxiety was going to return (Synofzik et al. 2012). Although initially an intermediate voltage for stimulation was chosen, the next day, the patient requested adjustment of the settings so that he could feel "a bit happier."

Especially when the treatment is received for anxiety disorder or depression, it might be difficult to delineate what should count as treatment and what as enhancement; moreover, it is unclear why we should care about that distinction at all. We should instead, as Synofzik et al. (2012) have argued, focus on what stimulation parameters are optimal in promoting patients' general well-being. Moreover, each mentally competent person should at least in principle be free to decide and act according to his or her personal preferences; arguments need to be given in the first place not for allowing the use of DBS enhancement, but for prohibiting it (Pacholczyk 2011; Synofzik et al. 2012). Further questions include: To what extent, emotion or mood enhancement promotes long-term well-being, psychosocial adjustment, functioning in the society, and happiness (see ▶ Chap. 76, "Ethics of Pharmacological Mood Enhancement"); which of those outcomes should be prioritized when they diverge; and who is to decide which of those outcomes should have priority.

Nontherapeutic Use of DBS: "DBS Should Not Be Used for Enhancement"

The case reported in Synofzik et al. (2012) brings to the fore the question about the permissibility of extending the use of DBS to enhancement uses. The "treatment of any disorder, including a mental disorder, is ethically permissible" argument legitimizes the use of DBS for accepted mental health disorders, excludes non-treatment uses, and leaves us uncertain about what to do in cases when medicalization of an

issue is especially strongly challenged (e.g., overeating or addictions). However, it relies on a problematic treatment/enhancement distinction (see ▶ Chap. 75, "Neuroenhancement"; ▶ Chap. 80, "Reflections on Neuroenhancement"). If we see the treatment/enhancement distinction as *normatively* relevant only to the extent that it traces cost-benefit ratio, the argument above could be simplified and strengthened by omitting the "treatment" criterion and instead simply focusing on the benefit (Synofzik and Schlaepfer 2008). Focusing on the benefit to a particular individual means that enhancement uses cannot be easily discounted ethically and at the very least warrant a careful consideration (Pacholczyk 2011).

As several authors put forward, it is ethically problematic to pursue brain interventions for frivolous reasons and this especially applies to relatively high-risk procedures like DBS (e.g., DeGrazia 2005a; Focquaert and DeRidder 2009). Since not many would encourage acting on frivolous reasons, there is a question of why there is an implied association between nontherapeutic uses and frivolity and who exactly decides what is and is not a frivolous reason.

For the purpose of the argument, let us consider three kinds of cases where a nontherapeutic use would be permissible on the basis of the cost-benefit ratio. Firstly, some patients who have already undergone DBS for treatment purposes may wish to control the stimulation settings for enhancement. The surgery risks have been already been taken, and so, the cost-benefit analysis will only include the risks associated with flexible stimulation played against possible benefits. Secondly, in some (admittedly rare) cases, a person might stand to greatly benefit from DBS if successful, and, while understanding the high risks, be willing to take them.[1] As argued by Pacholczyk (Pacholczyk 2011), the individual does not have the obligation to convince others that their values, acceptance of risks, and value attached to certain benefits are correct – what they are required to do is to know, understand, and weigh the risks, uncertainty, and the kinds of benefits that are likely. As long as they do, it is they who determine whether an intervention is worth trying. Thirdly, a nontherapeutic (but also technically non-enhancing) use might be envisaged when individuals want to be implanted with DBS for reasons having to do with pushing the boundaries of science and medicine. For example, a neuroscientist might want to perform a variety of cognitive tests, while she undergoes DBS to generate new knowledge. Then DBS would not be in that person's medical interest, and perhaps not in that person's narrowly construed self-interest (as there may be no strong expectation of improvement in cognitive or emotional capacities that would benefit the individual), but still can be in a widely understood self-interest that reflects their values related to the exploration of scientific questions. The three discussed cases demonstrate that it is unjustified to discount all enhancement uses as "frivolous" or necessarily ethically problematic on the basis of cost-and-benefit analysis alone.

However, DBS neurosurgeons face another set of questions before endorsing nontherapeutic use. Some questions and issues to consider include: (a) the fact that

[1]Doctors' and society's reasons to either provide access to the intervention or not are a separate issue

refusing DBS might in fact mean *denying benefit*, and therefore should be carefully considered and justified (or re-considered), (b) questions about who funds the physician's time and costs associated with surgery and the follow-up, (c) issues of priority: What place should be given to nontherapeutic uses in the context of limited expertise and physician time; this question fits into a wider array of issues that has to do with prioritizing therapy and clinical research with patients from different patient groups, suffering from conditions of varying severity and urgency, (d) the influence that nontherapeutic use might have on the public attitudes toward DBS in so far as they influence the development and application of the technique.

Identity Objections to DBS

Since the use of DBS in Parkinson's disease, an increasing number of commentators have raised and explored philosophical and ethical worries about its impact on selves, personalities, and persons (Hildt 2006; Glannon 2009; Müller and Christen 2011; Lipsman et al. 2009; Schechtman 2010; Synofzik and Schlaepfer 2008; see ► Chap. 25, "Impact of Brain Interventions on Personal Identity"; ► Chap. 22, "Neuroethics and Identity"; ► Chap. 23, "Neurotechnologies, Personal Identity, and the Ethics of Authenticity"). Merkel et al. (2007) point to the widespread philosophical worry that one's personal identity might be compromised as a result of brain interventions: "The fear is often expressed that an individual may no longer be "the same person" he or she used to be prior to an intervention in the brain" (p. 4). The concern about the altering of fundamental aspects of one's self, and thus one's personal identity, might be especially salient in the case of DBS, because the changes can be effected relatively quickly and be clearly causally linked to DBS.

Although everyday conversations may casually include phrases such as "she wasn't herself," or "he is not the person he used to be," in philosophical discussions, "persons" and "selves" tend to be highly specific, technical concepts, which have been developed over decades, if not centuries, of intense examination of our intuitive responses to various cases and scenarios. The concept of numerical identity grounds an understanding of how something can continue to exist despite undergoing significant change (DeGrazia 2005b). However, the question of personal identity persistence is not only a question of numerical identity, but also concerns the identity of a particular *person*.

Psychological Continuity Approaches to Identity: "DBS for Neuropsychiatric Disorders Should Not Be Used Because it Threatens Personal Identity"

According to the psychological approach, our personal identity consists (at least partly) in some sort of psychological continuity. In most psychological theories (e.g., Locke 1975 [1694]; Parfit 1984; Perry 1972), the relevant type of continuity is a continuity of experiential contents, or, in other words, the maintaining of

psychological connections over time (Olson 2003). Examples of such psychological connections include having an experience and later remembering it, forming an intention and later acting on it, and the persistence of certain beliefs, desires, and character traits. In other psychological theories (e.g., Baker 2000; McMahan 2002; Unger 1990), by contrast, the relevant type of continuity is the continuity of one or more basic psychological capacities, which may persist despite loss of memories and other experiential contents (e.g., a basic capacity for reasoning or the capacity for conscious experience).

Yet, in either of these philosophical stances, it is unclear how disruptions in psychological continuity would translate into ethical objections or ethical reasons to act. To arrive at such an ethical imperative, we need further arguments: whether psychological continuity is valuable, and whether that value is sufficient to determine what we should do and why (Focquaert and DeRidder 2009; Synofzik and Schlaepfer 2008; Witt et al. 2011). Assume that for various reasons, life-shaping events, periods of reading too much of mind-tinkering philosophy, a marked change in social environment and social roles played, moving to a different country, an accident, illness, etc., the psychological continuity link is too weak to provide a sufficient connection between different selves. How that would translate into moral reasons to act remains unclear. Should I make sure I stay sufficiently similar to myself now? Should I change slowly to maintain sufficient psychological connections? Do I have an obligation to struggle to re-gain my previous way of being? Is an attempt to radically reinvent myself an unquestionably morally dubious enterprise? If I could radically reinvent myself and no other ethical objections apply, would it be wrong for me to reinvent myself solely in virtue of this being a change that threatens psychological continuity, or results in a different self? It is far from clear. Therefore, even if we assume that psychological connections are severed by DBS (and this is not clear), this does not necessarily imply an ethical imperative not to undergo DBS.

Perhaps, if we are going to drastically change career paths, have children, marry, permanently move countries, think about taking antidepressants or other medication or decide whether to undergo DBS, or make any other potentially personality- or identity-changing decision, we indeed should ask ourselves, "How is it going to change me? How do I understand myself? How comfortable am I with the prospect of radical change? Although reflecting on psychological approaches to personal identity gives an opportunity to reflect on how we think about *ourselves* and about *our selves*, it does not indicate that we should act in a certain way." Therefore, as with other significant decisions, the possibility of radical change is an *important consideration*, but a prima facie *weak objection* to the use of DBS specifically.

Narrative Identity: "DBS for Neuropsychiatric Disorders Should Not Be Used Because It Cannot Be Incorporated Into a Self-Constituting Narrative"

Narrative accounts of identity typically pose that in practice, we create the sense of who we are through the construction of an autobiographical self-narrative

(see ▶ Chap. 24, “Dissociative Identity Disorder and Narrative”). Those self-narratives are commonly thought to be means by which we order both voluntary and involuntary aspects of our experiences, give and re-evaluate their meaning and importance, and understand and give meaning to our lives. It is often posited that construing self-narratives is very important, if not necessary, for a full and flourishing life.

Schechtman’s Objection to the Use of DBS: “DBS Threatens Personal Narrative Identity Because Narratives After DBS Do Not Fulfill the Articulation Constraint”

An influential account of narrative identity, and one that has been explicitly applied to the ethical assessment of DBS, is that of Schechtman. Schechtman (1996) distinguishes a re-identification question (what makes someone the same person over time, as in Parfit 1984) and characterization question (what it is to be a particular person). In the narrative account of identity, the focus is on whether a subject “creates their identity by forming an autobiographical narrative—a story of his life” (1996, p. 113). Not all narratives can be identity-constituting and Schechtman proposes that for a narrative to be identity-constituting, it must satisfy two constraints. First is the articulation constraint (the person must be able to provide some account of her history, her life situation, and her motivations) and another is the reality constraint (the self-narrative must be coherent with basic facts about how the world is).

Schechtman (2010) considers the use of DBS to be a threat to narrative identity. Personality changes that result from DBS, Schechtman argues, are at odds with the articulation constraint on identity-constituting narratives according to which “the narrator should be able to explain why he does what he does, believes what he believes, and feels what he feels” (1996, p. 114). When the causes of actions can be traced back to the influence of DBS, patients will not be able to explain how their actions flow from their desires, beliefs plans, and projects – because they do not. Discussing a hypothetical case of a patient who experienced profound personality changes after DBS, she states that “his current passions and interests—the things he takes as reasons—were caused by manipulation of his brain” (2009, p. 85).

Arguments Against Schechtman’s Objection

However, Schechtman’s conclusion might be not satisfactory on her own account. Schechtman concludes that DBS threatens narrative identity despite acknowledging that “since narrative is a dynamic notion, continuity of narrative is thoroughly compatible with even quite radical change.” (2010, p. 140) As Baylis (2011) rightly notices, Schechtman’s account leaves open the possibility that personality changes can be successfully integrated into a subject’s autobiographical narrative.[2] There is no reason to think that a subject will necessarily be unable to provide a satisfactory

[2]This holds whether or not a change in a given trait was intended. Narratives are typically thought to incorporate both voluntary and involuntary aspects of experience.

account of her history, life situation, and motivations; to narrate parts of her life in a self-conscious way; to render her self-narrative intelligible. Suffering and fighting a disease, thinking about DBS as a treatment option, the process of consent to DBS, the period of adjustment of settings, etc., can all form part of such a narrative.

It therefore seems that Schechtman relies on an implicit assumption that the mechanism of change matters crucially; yet, the reader is left in the dark as to why the involvement of a technological or medical means should be viewed with a *special* suspicion. One can wonder why, if it coincidentally happened so that either a sudden and dramatic life experience or a month of practicing qigong produced exactly the same physiological changes in brain function (and resulted in the same profile of personality changes), we should view this "natural" way of personality change with lesser suspicion than the changes that result from DBS.

A more charitable reading of Schechtman may get at some of our intuitions as to why a change of values, beliefs, or character traits following DBS would be problematic: It is not that DBS is problematic in virtue of it being a technological means of affecting change, but rather that the intervention belongs to a class of change-affecting events which are *difficult to make sense of within a personal narrative*. Perhaps a shift in views after an intense qigong practice or a life-shaking event could be equally problematic, if unaccompanied by reflection and integration of the new stance toward life, including giving epistemic and genealogical reasons for this stance. However, it seems that Schechtman's claim – that changes after DBS *cannot* be incorporated into a narrative– is too strong. Perhaps, DBS can in some cases undermine a person's narrative, but if a person could reinvent a narrative following severe personality changes due to head trauma, there is no obvious reason that a person who undergoes DBS could not. Thus, rather than being a strong objection to DBS under all circumstances, Schechtman's highlights challenge that DBS could create.

Another related, but separate worry would be that of epistemic justification for the changed values, beliefs, and character traits. This epistemic problem could be especially important if new values, beliefs, and character were *less* justified than the previous ones. However, in situations when previous justifications were weak (e.g., a depressed patient could hold a belief about him or herself being worthless as a result of childhood trauma), justified in the past but not the present ("My life is full of emotional pain" for a formerly depressed patient) or equally well or more poorly justified than a new belief (e.g., "I'm a conservative because my father was a conservative," "I'm a liberal because that is my fancy after DBS"), the degree of justification of the beliefs does not change, which would further qualify the strength of the objection.

Arguments Against the Strong Ethical Narrative View and the Strong Psychological Narrative View

Moreover, one can criticize the ethical narrative premise which states that a coherent and continuous narrative is necessary (or at least necessarily highly conducive) to a flourishing life. For example, Vice argues that if we take the narrative view "seriously" and "literally," it requires that we cast ourselves as "characters—usually the protagonists—of the stories we tell or could tell about ourselves" (2003, p. 93) and

points out the harm of associated self-deception, the risk of constraining autonomy, and being inauthentic. Mackenzie and Poltera (2010) reject the conception of narrative self-constitution that underpins the "story-telling" critiques (Strawson 2004; Vice 2003) and argue that they present narrative accounts as more rigid and literal than they are. Perhaps Strawson's and Vice's arguments apply more readily to more demanding accounts of narrative identity.

For example, Ricoeur's (1984, 1985, 1988, 1992) account of narrative identity is sometimes seen as imposing stringent criteria of structural unity of the story and homophony, which, as critics argue, may mean that meaningful and important experiences would go unnoticed, trivialized, or repressed (e.g., as in Maan 2010; Muzak 2007). On the other hand, Ricoeur's approach can be seen as a response to a perceived postmodern fracturing of the subject, and loosening the criteria too much risks making the narrative indistinguishable from a description or a dream sequence, thereby resulting in the loss of what makes a narrative identity specifically *narrative*. This discussion rooted in the literary tradition has its analogue in discussions within the field of narrative psychotherapy (e.g., Hermans 2003; Hermans and Dimaggio 2004) and the issue of the stringency of criteria for a narrative account of identity remains open. Even if indeed the full blow of Vice's and Strawson's claims here are taken only by the more demanding narrative views, the questions about justifiability of the ethical narrative thesis and the psychological narrative thesis remain.

First, the question is whether people indeed think about themselves in narrative terms. Although the conclusion will depend on the identity criteria posited by a particular theory of narrative identity (a conceptual issue), it is also an empirical question. In the absence of convincing evidence either way, it is plausible to assume that there are some people who understand their own lives through an elaborate narrative and evoke it explicitly on regular basis, others who re-construe and evoke an otherwise transparent self-narrative only when prompted by circumstances, and those who do not construct their lives through and in a narrative that would fulfill criteria for an identity-narrative. The latter sort of people may not be particularly reflective; suffer from a mental health issue that undermines their capacity to form complex narratives; or be highly reflective but assign little importance to a consistent narrative line, while, perhaps, attending to current reflectively endorsed interests, desires, and preferences.

Although according to the ethical narrative view, the lives of the last group are *necessarily* less meaningful or flourishing, it is a very strong thesis. There may be an aesthetic allure in a Ricoeurian view of fully flourishing life as life that is "complete," but I doubt whether such an aesthetic preference translates into an epistemic or moral imperative to lead or even aim at such a life. Thus, the move from how *we might* construe ourselves through the process of creating an autobiographical identity narrative to the conclusion that construing of such personal narrative is *necessary* for a meaningful or flourishing life lacks strong justification. In medical practice, I see no strong reason to favor a narrative identity view (and accept the potential objections to DBS coming with it) *if* the patient does not endorse or care about it.

A related objection is rooted in an observation that *not all identity narratives are good for you*. Narrative scholars have been long comparing well-being-promoting and autonomy-promoting and -undermining narratives (Brody 1994; Farkas 2013;

Frank 1995; Morris 2012; Sontag 1978), both in medicine and psychiatry. Even if we were to accept the strong ethical narrative thesis that narrative is necessary for a flourishing life, recognizing the deleterious aspects of some narratives opens the door to the conclusion that one might be better off in a state of narrative-less existential puzzlement rather than stuck in the rut of a harmful narrative.

Implications of the Narrative Approach to Identity for the Assessment of DBS

Claims about what identity is all about are an interesting area for both personal reflection and philosophical inquiry, but we should perhaps maintain an amount of normative liberalism when transferring those debates into the applied sphere of healthcare provision. Although Schechtman's claims seem to be too strong to ground a strong blanket objection to the use of DBS, the narrative approach might help us to explore how the issues of identity mediate the translation of side effects and symptomatic improvement into changes in well-being.

Both illness and treatment may cause substantial change and disruptions in peoples' lives. As patients come to terms with their illness, creating illness narratives (Frank 1995; Phillips 2003) could enhance the sense of self and agency if it enables the agent to make sense of their experiences, including the experience of illness (Mackenzie and Poltera 2010). Treatment can disrupt previously attained equilibrium and may profoundly affect patients, their spouses, and their broader social environment (Agid et al. 2006; Schupbach et al. 2006).

Since reports of patients' understandings of the meaning of biomedically induced personality and behavioral changes perhaps most famously in reported in Kramer's *Listening to Prozac* (1994), it is clear that the influence of an illness, treatment, and side effects on patients' well-being is shaped by patients' ways of constructing an understanding of who they are, their openness to change of personality, ability, and relations to others, as well as perspectives on biomedical means of treatment. Those issues have not received broad attention despite the fact that, as DBS treatment is extended to neuropsychiatric disorders, we might anticipate their impact on the psychosocial adjustment of patients (Bell et al. 2009).

Conclusion and Further Directions

The application of DBS for neuropsychiatric disorders and enhancement is controversial, despite promising results of clinical trials for several conditions and the prospect of helping patients for whom nothing else has worked. The rhetorical evocations of the history of psychosurgery, the concepts of invasiveness and reversibility, and the therapy/enhancement distinction may unjustifiably bias the examination of costs, benefits, and moral assessment of the purposes that DBS could be legitimately put to. On the other hand, objections to the use of DBS are a good starting point for clarifying how the technology can serve us best. Worries

about mind control, although weak as an objection to the current use of DBS, draw our attention to the importance of considering dual-use, regulating with one eye on the future of DBS and including the consideration of users' liberty to choose and modify stimulation. Objections from personal and narrative identity are not strong enough to warrant halting the use of DBS, but further research could use narrative approaches to understand and improve the way DBS impacts the life of users.

Ethical Implications of Brain Imaging

Neuroimaging Neuroethics: Introduction

Abstract

This section addresses some prominent neuroethical issues raised by new neuroimaging technologies. These include the potential for misinterpretation of neuroimages; combating this requires a better understanding of the difficulties and pitfalls in interpretation. Applications of neuroimaging introduce other ethical considerations. Discussed are the ethical implications of the emerging ability to assess disorders of consciousness with imaging in clinical settings, privacy concerns raised by the potential for mindreading; lie detection; and the ethical conundrums that will face us with the emerging potential for neuroimaging to provide predictive information about people's future behavior and disease.

Introduction

The ability to image brain structure and function in the intact, living, and behaving human raises a number of neuroethical questions regarding the proper interpretation, use, and limits of these new imaging technologies. Some questions are the

same or very similar to questions raised by other technologies, some are old questions in new guises, and some are specific to the technological and scientific challenges of neuroimaging. This section aims to address a spectrum of these neuroethical issues, from issues regarding interpretation, to those raised by potential applications.

Overview

Functional neuroimaging with fMRI is a highly technical, data-rich, and statistically complex endeavor. Unlike most highly technical and expensive scientific research, the technological sophistication of neuroimaging is almost paradoxically paired with an unprecedented ease of access to virtually anyone in academia or medicine. Its wide availability and ease of generating data mask the difficulty inherent in designing insightful and interpretable experiments. Good and fruitful neuroimaging studies are not trivial to design, and even these are challenging to interpret. Ethical applications of neuroimaging are predicated on sound interpretation. Thus, it is critical that researchers in neuroimaging and those applying neuroimaging results to real-world problems must be sophisticated producers and consumers of neuroimaging data. To that end, any complete neuroethical discussion of the area ought to include a tutorial on methods and pitfalls of neuroimaging research.

The ethical implications of neuroimaging abound. Standard use of neuroimaging for research purposes sometimes reveals brain abnormalities or other incidental findings with potentially grave consequences for the subject. Researchers must be aware of the statistical basis for interpreting the accuracy of such findings, as well as know the best procedures for informing the subject about these findings, with both her physical and psychological well-being in mind.

Neuroimaging has ethical implications not only in research studies, but in clinical medicine as well. Neuroimaging is poised to revolutionize some areas of medicine. Disorders of consciousness affect hundreds of thousands of people, and until recently diagnoses were made purely on a behavioral basis, with some people characterized as in a minimally conscious state, and others in a persistent vegetative state. Misdiagnosis of these conditions is pervasive (by some estimates, 37–43 %), and can have profound implications for medical strategies, pain management, and end of life decisions (Schnakers et al. 2009). As Demertzi and Laureys relate in their chapter, ▶ Chap. 41, "Detecting Levels of Consciousness," recent neuroimaging studies have provided novel tools for diagnosis and management of patients with altered states of consciousness. Perhaps most exciting is the potential avenue that brain imaging technologies provide to communicate with patients who are aware and cognitively intact, yet unable to respond verbally or behaviorally to instructions. Neuroimaging opens up the possibility that communication can be restored with these patients through associating responses with different imaginative tasks that have distinct neural signatures. The potential power of this mind-reading technique is coupled with a set of unique ethical challenges regarding how to interpret the capacity for autonomous and potentially momentous decision-making in patients whose abilities and lucidity are impaired to uncertain degrees and fluctuate over time.

Functional neuroimaging gives researchers some ability to infer aspects of mental state or behavior from brain activation patterns. Since all thoughts are due to brain activity, in principle it should be possible to correlate different thought contents with details of brain activation. In practice this is not possible except at a relatively coarse-grained level. The reasons for this are several: the spatial and temporal resolution of neuroimaging data is too low to capture the full spatial and temporal detail of brain dynamics; the signal-to-noise ratio is low. Researchers usually average multiple trials together to combat the noise in the data, thus losing some detail. Individual variability in brain structure and function suggest that no two brains will have identical structure-function relationships, which would mean that activity-meaning correlations would have to be mapped individually. Despite these limitations, there are also regularities evident across many subjects that can be exploited in order to allow some inferences about mental content (Roskies forthcoming). In recent years, headway has been made in understanding representations of semantic meaning for nouns, creating generative models, and reconstructing visual content from brain activation by perceptual stimuli. The limitations of imaging techniques provide reason to be skeptical of the prospect of being able to read propositional thought contents of people's minds, and very skeptical about abilities to do so covertly or without consent of the subject. On the other hand, there are less specific inferences one could make about content that could still raise ethical questions about the importance and limits of privacy. Roskies discusses some of these privacy issues in the chapter on Mind-reading.

Neuroimaging provides some traction on the perennial question of whether a person is lying or telling the truth. William Marsden, the inventor of the polygraph, was also the creator of Wonder Woman, the comic book heroine who had a golden lasso that could elicit truth-telling form those caught in its coils. People frequently think that neuroimaging has the promise to be a golden lasso – that we will be able to distinguish deceptive from honest answers by looking at brain activation data. Although neuroimaging has identified a constellation of brain areas that are reliably more active during lying than truth-telling in laboratory tests, no brain region is active in all such tests, and none that alone are sufficient for distinguishing honest from deceptive answers. Moreover, the vast majority of experiments meant to demonstrate the ability of neuroimaging to identify lying have used paradigms of questionable ecological validity – that is, they are investigating behaviors that are importantly unlike real-world cases of lying. Finally, even though a few experiments claim to have high rates of success in these discriminations, the difficulty in establishing error rates and the absence of base-rate information hampers application of these studies. Without known error rates and an understanding of the prevalence of lying in the relevant population, we cannot determine the actual reliability of these tests. Thus, despite promising results in laboratory settings, use in real-world applications from screening to forensic contexts seems premature. In the chapter on Mind-reading and privacy, Roskies touches on the problems plaguing real-world application of lie-detection studies.

Neuroimaging studies correlate brain activation patterns with tasks, behaviors, or phenotypes. Assuming that the sample upon which the correlations are based is

a representative one, one could potentially use neuroimaging predictively or diagnostically. Indeed, recent studies show that neuroimaging holds promise for diagnosing certain diseases, and for predicting recidivism in a penal population. The ability to predict behaviors and disease states brings with it a host of knotty ethical problems. For example, in the wrong hands diagnostic information could be used to discriminate against potential hires, insurance consumers, etc. Perhaps more disturbingly, one could imagine pressure to act upon predictions of future dangerousness, even in cases in which the subject has not exhibited any violent behavior. The shadow of "Minority Report", a movie in which prevision licensed arrest of future perpetrators before they committed crimes, looms large. It goes against our deep commitment to the principle that people are innocent until proven guilty, and pits our science against instrumental reasons for averting future harms. However, it is essential to realize that these methods only give statistical reasons for prediction, and that in any given case the predictions could be misleading. Not everyone with a genetic predisposition for a trait exhibits that trait, and because of statistical issues and complexities of brain organization and function, the same can be said of brain data. A discussion of the neuroethics of neuroimaging for prediction must address these complexities.

Conclusion and Future Directions

Neuroimaging is a fast-moving and evolving field, driven as much by advances in data analysis as by biological insight. No doubt as imaging techniques become more powerful and our picture of brain organization and function becomes better articulated, ethical issues will arise as practical realities that now seem only hypothetical, and perhaps entirely novel issues will raise their heads. For now, neuroimaging poses significant enough challenges, challenges that need to be addressed by technically-informed, philosophically sophisticated, and clear-minded analysis.

Detecting Levels of Consciousness

Abstract

Patients with disordered consciousness due to brain injury pose medical and ethical challenges. Rates of clinical misdiagnosis of "vegetative"/unresponsive, minimally conscious and locked-in syndrome states remain challengingly high. Clinical misdiagnosis raises profound ethical concerns in terms of medical management, treatment of pain, and end-of-life decisions. Therefore, valid diagnosis is of utmost importance in clinical settings. A number of neuroimaging and electrophysiology studies now suggest that some behaviorally "vegetative state" patients may nevertheless show atypical cortical activation during resting state conditions; in some cases, they are able to follow commands or even communicate through willfully modified brain activity. Advances in investigating disorders of consciousness with neuroimaging techniques promise to lead to a more accurate understanding of individual patients' cognitive abilities and to shed light on the gray zones of these clinical conditions.

The formulation of an ethical framework which will strike a balance between the protection of these patients and further research on disorders of consciousness is an ethical, clinical, and scientific demand.

Introduction

Consciousness is a multifaceted term for which there is no universal definition (Zeman 2001). Clinical experience teaches that we can define consciousness operationally, by reducing it to two components: wakefulness and awareness (Posner et al. 2007). Wakefulness refers to the level of alertness, and it is supported by the function of the subcortical arousal systems in the brainstem, the midbrain, and the thalamus. Clinically, wakefulness is indicated by eyes opening. Awareness refers to the content of consciousness, and is thought to be supported by the functional integrity of the cerebral cortex and its subcortical connections. Awareness can be further subdivided into awareness of environment and of self (James 1890). Clinically, awareness of environment is assessed by evaluating command-following and by observing nonreflex motor behavior, such as eye-tracking and localized responses to pain. Awareness of self, a more ill-defined concept, can be assessed by the patients' response to self-referential stimuli, such as the patients' own face in the mirror (Vanhaudenhuyse et al. 2008b). An illustrative example of the relationship between the two components of consciousness is the transition from full wakefulness to deep sleep: the less awake we are, the less aware we are of ourselves and our surroundings.

Developing technologies have made a significant impact on the assessment and management of patients with profoundly impaired consciousness. Neuroimaging techniques such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET), as well as electroencephalography (EEG) and evoked potential studies, have offered the possibility of objectively approaching cognitive processes in patients who are otherwise incapable of intelligible or sustained behavioral expression. Indeed, patients in a vegetative state (VS; Jennett and Plum 1972), recently coined unresponsive wakefulness syndrome (UWS; Laureys et al. 2010), do not show any signs of awareness of themselves or their environment in spite of preserved wakefulness levels as evidenced by eye opening. Some patients, however, may show minimal signs of consciousness but remain unable to reliably communicate with their environment. For this patient population, the term "minimally conscious state" (MCS) is used (Giacino et al. 2002). MCS was recently subcategorized based on the patients' complexity of behaviors (Bruno et al. 2012). More particularly, MCS + describes high-level behavioral responses, such as command-following, intelligible verbalizations or nonfunctional communication (i.e., responding to incorrectly or inconsistently to questions), and MCS − describes low-level behavioral responses, namely, visual pursuit, localization of noxious stimulation, or contingent behaviors like appropriate smiling or crying to emotional stimuli (e.g., patient cries only in her mother's presence). Patients for whom nonbehavioral evidence of consciousness or communication are only measurable via ancillary testing such as fMRI, PET, EEG, or evoked potentials can

be considered to be in a functional locked-in syndrome (LIS) (Bruno et al. 2011b). This is different from the classically defined LIS, where patients are fully conscious but their only means to communicate is by moving their eyes or their eyelids following a certain code, such as look up for "yes" and look down for "no" (American Congress of Rehabilitation Medicine 1995).

The Ethical Imperative

Early since disorders of consciousness appeared in the clinical setting, clinicians, scholars, theologians, and ethicists began to wonder what it is like to be in a state of profoundly disturbed consciousness (e.g., Thompson 1969). Are these unresponsive patients in pain, and can they even suffer from it? How can their quality of life be assessed? And more importantly, is a life in such severely restricted conditions worth living? Is this a question these patients can even weigh in on? Controversies of these kind mainly stem from how different people regard indefinite survival in disorders of consciousness (Jennett 2002; Demertzi et al. 2011a).

Despite the general view that quality of life is diminished in disease as a result of limited capacities to functionally engage in everyday living, these attitudes are formulated from a third-person perspective. Consequently, only rough estimations about what it is like to be in such a situation can be made. For instance, an analysis of public media reports on Terri Schiavo (a patient in a VS/UWS; e.g., Quill 2005) revealed that in some cases, the patient was described as feeling discomfort, which was incompatible with her clinical state (Racine et al. 2008). This implies that nonmedical individuals, whose opinions are supposedly represented – at least to a certain degree – by media reports, may be biased toward residual cognitive function of patients with consciousness alterations. Such bias could be attributed to the fact that patients' quality of life evaluations are made from the perspective of healthy individuals who tend to underestimate patients' subjective well-being (Demertzi et al. 2013b). Indeed, we recently showed that patients in LIS expressed a positive subjective quality of life contrary to what could be expected in this condition (Bruno et al. 2011a). As mentioned above, patients with LIS do not suffer from disorders of consciousness. However, LIS patients constitute a nice control population for patients with disorders of consciousness due to their resemblance in terms of physical disability and possibly common history (i.e., LIS patients can have been in comatose-like states). In this self-reporting survey, it was shown that the majority of patients in a chronic LIS, despite mentioning severe restrictions in community reintegration, professed good subjective well-being (Bruno et al. 2011a). The self-reported happiness status was associated with longer duration in this condition, namely, patients reported being happier over time, the ability to produce speech via assisting technologies, and lower rates of anxiety. These findings suggest that healthy persons who are not in direct contact with this patient population can have distorted pictures as to what is life in these severely constrained situations. But what about health-care workers opinions' who are more likely to interact with patients?

When clinicians were recently asked to express their opinions on possible pain perception in VS/UWS, a significant number of medical doctors ascribed pain perception in these patients (56 %) despite formal guidelines suggesting the opposite (e.g., The Multi-Society Task Force on PVS 1994). For MCS, there was no discrepancy in opinions and the majority (97 %) of respondents thought that MCS patients feel pain (Demertzi et al. 2009), in line with neuroimaging data strongly suggesting preserved pain perception in MCS (Boly et al. 2008). The issue of pain management in unresponsive patients becomes more challenging when withdrawal from life-supporting treatments, such as artificial nutrition and hydration, has been agreed upon. In a wide survey around Europe, we showed that health-care workers' opinions on end-of-life in disorders of consciousness differed depending on the diagnosis (i.e., respondents supported treatment withdrawal more often for VS/UWS than MCS patients), professional background (i.e., when physicians imagined being in MCS, they preferred more often to be kept alive compared to paramedical professionals), region of origin (i.e., Northern Europeans agreed with treatment withdrawal more often compared to Central and Southern European respondents), and religious beliefs (i.e., religious respondents agreed less with treatment limitation in both VS/UWS and MCS compared to nonreligious ones) (Demertzi et al. 2011b). These data show that personal opinions about ethical issues in disorders of consciousness differ and hence different clinical practice can be expected. For example, in the European survey, the majority of participants approved to stop treatment in VS/UWS (66 %) more than MCS (28 %). In this case, VS/UWS patients may run the risk of being left without administration of opioids or other analgesic drugs during their dying process (Laureys 2005; Fins 2006) on the grounds that they are unable to experience suffering due to hunger or thirst (Ahronheim and Gasner 1990). We recently showed an interaction between opinions on pain perception and end-of-life preferences. More particularly, there was a negative association between these two types of attitudes for the VS/UWS, namely, that participants agreed with treatment withdrawal when they denied these patients could experience pain (Demertzi et al. 2013a). From such studies on clinicians' attitudes and attitudes of patients' families (e.g., Kuehlmeyer et al. 2012), it becomes evident that medical and ethical controversies continue to exist for patients with disorders of consciousness. In order to resolve them, at least to a certain degree, we need to improve our current understanding of how these patients function. The use of objective biomarkers may help us to better determine the differences in underlying pathophysiology characterizing the clinical entities of consciousness. Consequently, clinicians are expected to learn about patients' values and preferences and to maintain clinical insight for changes in patient's status with the patients' best interests in mind (Jox et al. 2012).

The Pursuit of Awareness

The past 15 years have provided an unprecedented collection of discoveries that bear upon our scientific understanding of consciousness in the human brain

following severe brain damage. Highlighted among these discoveries are unique demonstrations that patients with little or no behavioral evidence of conscious awareness may retain critical cognitive capacities. These first scientific demonstrations support that some severely brain-injured patients in longstanding conditions of limited behavioral responsiveness may nonetheless retain latent capacities for awareness. Such capacities include the human functions of language and higher-level cognition that, either spontaneously or through direct interventions, may reemerge even at long-time intervals or can remain unrecognized.
